The Académie de médecine has adjourned until October 3. At its last session Dr. Routier, surgeon of the hospitals of Paris, reported a case in which the abdominal aorta was sutured. A diagnosis of hydatid cyst, based on the reaction of Weinberg, was made on a young man of 24 who complained of pains in the left hypochondrium. In the course of the operation it was ascertained that the tumor was in reality a solid one covered by a very vascular membrane adhering to the aorta. It was enucleated with great difficulty and the tags of the enveloping membrane were clamped off by forceps. One of the last adherent points was clamped off and the tumor removed. Each pair of forceps was successively replaced by a ligature. At the moment of tying the last one, a jet of blood burst into the surgeon's face. Compressing the aorta with his left hand, Dr. Routier placed on the orifice in the aorta, which was as large as a brachial artery, two hemostatic forceps which stopped the hemorrhage. But this was considered only an emergency measure and it was to be expected that on the removal of the forceps a fatal hemorrhage would ensue. A second operation was, therefore, necessary and on the next day the patient was anesthetized. With needles threaded with fine silk an attempt was made at first to pass a ligature behind the forceps but the needle and the thread broke. Taking then the needle of Reverdin, which is used in intestinal sutures, Routier passed a catgut suture into a fold of the aorta under the forceps and tied it. The two ends of the suture were then passed around and tied solidly under the two forceps. Success was complete. No blood ran when the forceps were withdrawn. A fragment of the epiploon nearby was placed over the ligature and the abdomen was closed. All went well; there was a temperature of 37 C. (98.6 F.) and 78 pulsations to the minute for eight days. In the night of the eighth day after an abrupt movement there was a kind of demisyncope, pain in the abdomen, facial pallor, perspiration of the skin and thorax. A secondary hemorrhage was thought of. This passed, however. The patient finally died on the sixteenth day. It was impossible to ascertain the cause of death, as autopsy was not permitted. This seems to be the third case of suture of the abdominal aorta.

Vaccination Against Typhoid Fever

The minister of war, M. Messimy, has entrusted to Dr. Chantemesse, professor at the Faculté de médecine de Paris, and Dr. Vincent, professor at the Ecole d'application de médecine et de pharmacie militaires du Val-de-Grâce, the task of applying among the troops on the Algerian and Moroccan frontier the method of antityphoid vaccination. This decision was taken in response to a resolution of the sanitary service of the province of Oran submitted by medical inspector Février, director of the sanitary service of the army to the consultant commission on military hygiene and epidemiology, which voted its approval. As in the armies of other countries, this vaccination will be entirely facultative.

The Dogs of the Sanitary Service

The use of dogs in the relief of the wounded was recently tried at Vincennes in the course of instruction of the sanitary service of the military government of Paris. Several men who were supposed to be wounded were hidden in various places on the plain. All the pseudo wounded were found in a few minutes. The trial was made as follows: The dog is sent off by his master in a given direction at various distances; he aids the wounded, takes his kepi and brings it back. The dog leads or, one might say, drags his master immediately to the spot where he found the wounded man without hesitation. In default of the kepi the dog hunts with his paw or his muzzle in the wounded man's pocket and takes his handkerchief, glove or some other object showing the identity of the man.

The importance of the use of such dogs is readily understood. Wounded men exposed for a long time on the field of combat may be exposed to attacks of birds of prey and in our colonial expeditions several have undergone frightful mutilation by the natives. The methods of combat, the arrangement of the troops during battle over a more or less extent of territory, modern long-range fire-arms, night battles —all these make the work of the ambulances very difficult. The number of men who disappear is always large because the relief of the wounded during action becomes constantly more difficult. The wounded who are too weak to call or to leave their shelters are abandoned unless the orderlies are accompanied by dogs who are used to searching for the wounded. It seems, therefore, that it is necessary for modern armies to possess dogs trained in the sanitary service.

The New Hôpital de la Pitié

The new hospital built to replace the old building of the hôpital de la Pitié has just been opened. It is a model building established at the cost of 11,000,000 francs (about $2,200,000) and comprises thirty-two medical and surgical buildings.

The Physician Not Always Obliged to Continue the Care of the Patient

While it is true that the obligation of a physician to respond to a patient's call is one imposed by conscience solely, the case is altogether different if the physician abandons his patient at a critical moment when his retirement may endanger the life and health of his patient. A Paris tribunal has recently decided, however, that the withdrawal of the physician is justified in some instances. The case which elicited this opinion was that of an obstetrician who withdrew because the patient or those around her were determined to select a nurse whose antecedents were unknown to the physician. The court held that this physician, in renouncing the responsibility and the fees of confinement acted honorably and was in a position to demand damages on account of the injury to his professional reputation through the unjustified action of his patient.

DRESDEN LETTER

(From a Special Correspondent)

International Hygiene Exhibition

DRESDEN, July 28, 1911.

A visit to the International Hygiene Exhibition at Dresden brings a number of surprises. First, one is surprised that in an exposition supposed to be international in character, the catalogues, explanations, labels, etc., are practically all in German. It was surely not too much to expect to find the labels and abbreviated catalogues in French and English.

Second, one is surprised that so large a proportion of the exhibition is commercial in character, containing much that is only remotely, if at all, connected with hygiene. While it is primarily a hygienic exhibit, apparently nothing has been refused admission that would help to make the exhibition a financial success. There are, as might be expected, many beer gardens over the ground, tobacco stores and the like. There are numerous "Coney Island" attractions and ingenious means of attracting the nimble penny. Photographing, copying or reproducing any of the exhibits is forbidden. The right to photograph was let to one photographer, who I was told gave 20,000 marks ($5,000) for the monopoly. Needless to say the enterprise long ago paid for itself.

The English-speaking nations are poorly represented in the exhibit. Great Britain was late in opening her exhibit, which though excellent in many ways, is hardly commensurate with the splendid sanitary achievements of that country. This is probably owing to the reluctance of the British Government to make an appropriation for the Dresden Exhibition, notwithstanding the fact that the British colony in Dresden had raised a handsome purse as a starter.

And the United States! There is nothing whatever to indicate that there is such a country. The only exhibit from the American continent is a small one from Brazil. The French, Swiss, Austrians, Russians and Spanish all have exhibits. The Japanese have an admirable exhibit, and one naturally recalls the difference in the medical management of the armies in the Spanish war and in the Russo-Japanese war. Not that American physicians were not alive to the importance of hygiene and sanitation, but the non-medical "men above" had not learned the lesson. Too much red tape, in fact. This characteristic and the indifference of our government officials to health matters may explain the failure of our physicians and sanitarians to obtain an appropriation for Dresden.

One is amazed at the completeness and the excellence of the educational and scientific exhibits. The care and expense involved in the preparation of the exhibition are extraordinary. Explanations have been made and demonstrations installed in order to make plain to the man in the street the anatomy and histology of the body, the functions of the organs, the needs of the body in food, air, exercise, clothing, etc., and yet any physician will find well spent the time he spares for a study of the health exhibit. The composition of the body, of the blood, of various food substances, of the excretions, etc., are shown by means of jars containing the exact amount of each constituent in a manner much more impressive than can be done by means of charts. Similar exhibits have been made elsewhere, but perhaps not to the same extent as here. One physician, a German, passing through the exhibit stated that it took him years to learn what here he might obtain within a few months. There must be at least 100 compound microscopes, some of them binocular, exhibiting tissues, cell growth and microscopic life; and there are many stereoscopes of the new type, adjustable for pupillary width (which sell here for about $14.00). There are admirable papier maché and wax figures of the human body and its parts, and an excellent series (in wax) of skin diseases, including the exanthems, and syphilis and lupus. There are exhibitions of beds for the sick, bath apparatus, healthful clothing, ventilating and heating systems, etc. The effort has been made to demonstrate the evil effects of tobacco, alcohol and other narcotics, corsets, tight shoes and the like. The care of infants and children, the value of exercise, care of the health in old age, the importance of proper nutrition, have been carefully shown with a view of making the exhibit of real value to the general public, who, by the way, throng the buildings and the grounds in the afternoons so densely as to make it inconvenient to get around. There are motion picture exhibits of silk-worm culture, the protective agencies of the blood (a magnificent representation of the clumping of bacteria in the blood), etc., the projection of microscopic life, and stereopticon lectures. Infectious diseases, tuberculosis and tropical diseases have had due attention. But to particularize is only to omit other features fully as good. This is certainly an exhibit of which the Germans may feel proud.

BUDAPEST LETTER

(*From Our Regular Correspondent*)

Budapest, Aug. 7, 1911.

Ancient Jewish Hygiene in the Dresden Hygiene Exhibition

Having spent my holiday in Dresden, I found many things of interest in the wards of the Jewish section, which attracted my attention with its descriptions of ancient hygienic institutions and laws approaching in perfectness many an institution and law of to-day.

The exhibition in Dresden devoted two spacious halls to the exhibits of the sanitation of biblical, ancient and medieval Jewry.

The thora being the foundation of the Jewish hygiene, a good part of the biblical and ancient class is occupied by the exhibition of thoras. Much attention is paid by the visitors to a thora about 1,000 years of age, written on red leather.

The walls are covered with Hebrew and German texts of Moses' hygienic laws. The inside of the hall is occupied by a plaster cast of King Solomon's lakes and water-works. Here we find books, drawings and plans on the water supply of biblical Jerusalem, ancient Jewish residences and reliquiæ found at excavations. Bricks, roofings, walls and fountains, drainings, sewers for the removal of droppings and photographs of household utensils are here in a great abundance.

A separate group deals with the housing, showing an evolution from tents to houses of mud and later of stone. The type of the ancient houses has scarcely changed in comparison with the houses of Palestinian and African Jews, or the tents of some nomad tribes.

Another group deals with the rules to be observed in eating and drinking. The customs at meals can be seen on plaster models. Here are pictures of old ovens, fireplaces, grain store-houses, models of flour mills and the reliquiæ of original grain-crushing stones. In contrast to these ancient things, we see exhibited the present foods, dishes and household tools of native Palestinian and African Jews.

In the medieval class the walls are covered with quotations from the Talmud, as the source of sanitary laws. One case is full with special instruments and apparatus for circumcision. One or two among them are real masterpieces of art. The series of circumcising instruments is most interesting, commencing with a knife, the handle of which is ornamented with rubies and diamonds, and ending with a simple knife suitable for being boiled and sterilized. Another case contains the sick nursing instruments which every parish had to procure for itself.

The ritual handling of the dead is represented by plastic models. This is supplemented by a collection of grave-stones and burial requisites.

An important feature of medieval hygiene of the Jews was the public baths. Here are bathing and washing requisites, together with a collection of hand-washing basins.

The management of meat is instructively illustrated by a series of pictures, showing the processes from the salting of the meat to its being dished up. A plaster cast shows the humanity of ritual slaughtering and the brutality of killing an ox with a blow. An anatomic preparation shows the bloodless heart of the animal, beside it, the killed animal's heart full of blood.

The exhibition is finished with a room furnished and fitted up entirely with original ancient furniture; a laid table awaits the advent of the Sabbath.

This Sabbath awaiting room, apart from its interesting historic and folk-lore aspects, stands as an expression of the social thinking of an ancient people, who made it a law to have rest on the seventh day of the week.

In the modern sections of the exhibition we meet with names of Jews from every land prominent in the domain of medical and hygienic sciences. Among them are Birch-Hirschfeld, Born, Cohnheim, Fränkel, Güartner, Remák, Hebra, Schwalbe, Weigert, Ascher, Askanazy, Kronecker, Loeb, Hein, Izraeli, Munk, Pollitzer, Fuchs, Haffkine, Koplik, Senator, Marmorek, Metchnikoff, Weil, Ehrlich, Wassermann, Landau. This list shows that the special Jewish hygiene and sanitary education of biblical and ancient times has not passed away without traces.

BERLIN LETTER

(*From Our Regular Correspondent*)

Berlin, Aug. 3, 1911.

Personal

Professor Reichenbach of Bonn has received a call to succeed Professor von Esmarch as director of the Hygienic Institute at Göttingen.

Professor Weber, formerly director of the medical clinic at Halle, celebrated the fiftieth anniversary of his doctorate.

Professor Jamin of Erlangen and Professor Umber of Altona have been nominated, neither one being given a preference, to succeed Professor Gerhardt in Bern.

Prohibition of Weapons to Students

In view of the numerous accidents which are caused by the hasty use of firearms by students, the Prussian school authorities feel obliged to issue a general prohibition of weapons for students of the higher schools. Every student who is found in possession of any kind of firearm or ammunition will be punished by expulsion from the school.

The Position of Physicians in the Criminal Statutes

In Germany there exists the peculiar state of affairs that, according to the construction of the criminal statutes, the physician is threatened with punishment even for professional treatment that is carried out according to established rules. A surgical operation which is undertaken without the express consent of the patient may, for instance, be treated as a bodily injury and the physician may be convicted on account of it. Inasmuch as at present a new criminal code is being prepared, physicians are bestirring themselves to have the paragraphs which threaten their professional activity removed or so modified that their construction will be less dangerous. On account of the importance of this matter the last Deutsche Aerztetag took it into consideration. The committee to whom the reports were referred, presented the following propositions which were adopted by the Aerztetag:

On account of the inclusion of medical professional treatment under the sections "Crime and attempts on the life" and "Bodily injuries," a legal uncertainty is produced which makes the business of the physician difficult and which is injurious to the public health. The Aerztetag expresses its opinion that treatment by a physician when it is conducted according to the rules of medical science and art should not fall in the criminal classification of premeditated bodily injury. The Aerztetag recommends the addition to the preliminary paragraphs of the criminal code, the following statement: "A person shall not be punishable who undertakes any action for the saving of a person or the property of himself or that of another from a present danger for which he is not responsible, and which cannot be removed in a more appropriate way, except when the danger is only slight or involves only the saving of property, unless the damage to be expected from the operation is disproportionately greater than the danger. One is not punishable who undertakes to save a person from a present danger not to be removed in a more suitable way than by an operation on the person himself, except when the danger is only slight."

To Limit Advertising Intended for the Laity

In Germany there exists the custom (less common in your country) of drug manufacturers advertising medicinal preparations, not only in the medical press, but also in the daily papers. Other firms place in the circulars accompanying their specialties recommendations of other remedies. The last Aerztetag has passed a resolution against this advertising business which favors self-medication by the public.

Average Length of Life of the German People

From the death-rates which give the number of deaths per 1,000 births at the end of the first, second, third, etc., year of life, the length of life, that is, the whole number of years that these 1,000 persons have lived, is obtained; this sum divided by 1,000 gives the average length of life for the individual. This number is called the average length of life. From the three published mortality tables for the entire German people, the following average life duration can be calculated: From 1871 to 1880, for men, 35.58 years; for women, 38.45; from 1881 to 1890, for men, 37.17; for women, 40.25; from 1891 to 1900, for men, 40.56; for women, 43.97. The average for men has risen 5 years in the last twenty years, that for women five and one-half years. Still Germany is behind many other European countries. In Sweden, the average length of life is about ten years higher than in Germany, in Belgium and the Netherlands about five years, and in France and England about four years. The chief reason for this difference lies in the considerable infant mortality of Germany.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Aug. 9, 1911.

An Embryo Found in an Elephant in the Vienna Zoological Garden

A few days ago the female elephant in the Vienna Zoological Garden died after having been ill for some weeks. The interesting patient had been treated by two professors of the Vienna veterinary high school. The predominant symptoms of the disease were anorexia and frequent attacks of what may be called swooning fits. When the animal died, it was examined by representatives of the museum of natural history, of the anatomic institute and the veterinary high school. A regular post-mortem examination was made, and it was a very difficult task, for the body weighed 1½ tons even after the enormous loss of blood. The most interesting finding of the necropsy was an embryo, completely developed as to macroscopic appearance, measuring 65 cm. and apparently 11 months old, thus lacking another eleven months to its maturity. This uncommon specimen was taken possession of by the anatomic institute. The mother elephant was found to have suffered from chronic gastro-intestinal inflammation with ulcerations of the anterior wall of the stomach. A detailed account of the findings will be published soon, while a good deal of the material obtained will need to be studied and worked up later on.

The Spread of Cholera in Austria

Since writing the last time about the appearance of cholera in this country (THE JOURNAL, June 24, 1911) the disease has claimed in Trieste, our chief port, over twenty victims. The infections were all traced to steamers coming from Italy, and in spite of very strict and careful precautions a spread could not be prevented. As it appears now, there are several foci from which the various cases of the disease have originated in the city. Much bitter comment has been heard concerning the attitude of Italy, in not reporting the presence of cholera in its districts to the other governments, as it ought to have done according to the last cholera convention. It is said here of Italy that actual cases of cholera have been officially "diagnosed away," so as not to prevent the influx of visitors to the country and the two exhibitions. In Austria, as soon as the cases occurring on board ships were traced to the neighboring country, the commercial traffic was placed under careful control. But before the measures went into effect, infection had taken place in several different localities. It is interesting to note that all cases observed afterward were among those persons who were under control as "suspects," having been found to be "carriers of vibrios," at the routine examinations of all persons in contact with a definite cholera patient. Therefore, the hope of the board of health that the outbreak will soon be suppressed is justified. Another source of danger of infection is the *Hinterland* of the Austrian coastline, where just now the Turks are fighting the Albanian tribes. Cholera has been found there too, and the low sanitary standard of these people means a real menace to that part of Europe. Therefore, the Austrian government has sent down a number of well-equipped physicians to these districts.

A Special Prize for Austrian Physicians

Two French practitioners, Dr. Meussand and Dr. Rivier, have notified the senate of the University of Vienna that they have placed at the disposal of this body a sum sufficient to yield yearly an interest of 1,000 francs ($200) for the purpose of sending an Austrian physician to Paris. The candidates must not have obtained their diplomas longer than four years ago, and must spend the prize in Paris, staying there at least three months in the hospitals pursuing scientific objects. The prize is granted in two equal sums, at the beginning of the Paris stay and six weeks later, respectively. This unusual but most welcome grant is intended to promote more intimate relations between the two famous continental medical schools, Paris and Vienna. At present, there is hardly any connection between the two save occasional visitors during the international congresses.

Effects of Agrarian Prohibition Tariffs on Meat Imports

The influence of our great agrarian proprietors on legislation is very powerful, and their political preponderance was the chief reason that some ten years ago a tariff was introduced in Austria making the importation of meat and living animals into this country impossible, because unprofitable. But owing to the constant rise in prices on all articles of food, frozen meat was imported this year from South America in limited quantities. It sufficed to show that it is possible to procure from abroad wholesome and healthy food at a considerably lower cost to the consumer. No sooner was this evident, than the landowners again exerted their influence to stop further importation of frozen meat. They succeeded. But then the population, especially the poorer part of the rural population, brought all influence to bear on the government to obtain cheap food. Medical men were at the head of the movement which wanted to "open the frontiers." They pointed out how much underfed the population is at present, and how much the consumption of meat per capita has decreased within the last few years in all Austrian towns. And they pointed out, too, how national defense would suffer, and has suffered already, because the recruits, underfed as they are, become less and less fit to be enlisted in the army. This latter argument seems to have had effect on the government, for now a commission for studying the problem of food has been appointed. But a more substantial gain is the permission for the importation of a certain quantity of frozen meat, which was wrested from the government. Once obtained, this concession will no doubt be necessarily increased, with or without the permission of the landowners. A similar conflict has broken out with regard to the supply of milk. Here the dairymen try to create a ring or a trust to push the price of milk to a higher level. The violent indignation of the urban population has for the moment averted the danger.

Marriages

Charles Martin Strotz, M.D., Philadelphia, to Miss Estella Erwin of McVeytown, Pa., at Cristobal, Canal Zone, August 2.

Burt D. Harrington, M.D., Flatbush, L. I., to Mrs. Florence Omlsted Randall of Hackensack, N. J., August 2.

Arnold Burkelman, M.D., to Mrs. Mary J. Lindsay Schallert, both of Los Angeles, Cal., August 17.

Edwin Holland Trower, M.D., to Miss Catherine Elizabeth Rush, both of Eastville, Va., June 28.

James N. Shearl, M.D., Middletown, Ill., to Miss Bertha M. Nicholson of Tower Hill, Ill., August 2.

Ira Stanley Pope, M.D., Chevy Chase, Md., to Miss Marie M. Spatola of Philadelphia, August 9.

James Edward Allgood, M.D., Liberty, S. C., to Miss Ruth Thompson of Inman, S. C., June 20.

Elisha B. Jackson, M.D., to Mrs. Lydia Ward-Hubbard, both of Aberdeen, S. Dak., July 31.

James M. Delevett, M.D., Baltimore, to Miss Mary E. Fitzhugh at Philadelphia, August 9.

Fred C. Jordan, M.D., Lewis, Iowa, to Miss Berma Bland of Des Moines, August 2.

Deaths

Alvin Allace Hubbell, M.D. University of Buffalo (N. Y.), 1876; one of the most prominent specialists on diseases of the eye of western New York and a prolific writer, died in Buffalo, August 10, of general arteriosclerosis, aged 65. After graduating with honors from the University of Buffalo, he studied diseases of eye under the late Dr. Samuel D. Gross in Philadelphia for more than a year, and then began his practice in that specialty in Buffalo; his ability was at once recognized and his practice rapidly increased. After his graduation Dr. Hubbell was made professor of ophthalmology in the Niagara University, Buffalo. In 1898, when this institution became consolidated with the University of Buffalo, he became professor of the same specialty in the latter school, and in the spring of 1911 he was made emeritus professor of ophthalmology. For several years Dr. Hubbell was surgeon to the Charity Eye, Ear, Nose and Throat Hospital, the Sisters of Charity and the Erie County Hospital. He was also oculist to the Lake Shore and Michigan Southern Railroad. He was a member of the American Medical Association, chairman of the Section on Ophthalmology, 1908-1909; one of the founders of the Buffalo Ophthalmological Club; president in 1908 of the American Ophthalmological Society and a member of the American Academy of Ophthalmology and Oto-Laryngology. He was the author of a number of articles bearing on his specialty, and in 1908 published a volume entitled "The Complete History and Development of Ophthalmology from 1800 to 1870."

Blencowe E. Fryer, M.D. University of Pennsylvania, Philadelphia, 1859; colonel, medical corps, U. S. Army, retired; one of the most prominent ophthalmologists of the southwest; died at Marquette, Mich., August 13. At the outbreak of the Civil War, Dr. Fryer entered the Army as assistant surgeon and passed through the successive grades to lieutenant colonel before his retirement in 1891, and received his promotion to colonel retired in 1904. While he was stationed at Fort Leavenworth, Kan., Major Fryer was called to the chair of ophthalmology in Kansas City Medical College, and was made permanent professor of that branch ten years later, and thereafter confined his medical work to diseases of the eye and ear. He was a member of the American Academy of Medicine, American Ophthalmological Society, American Academy of Ophthalmology and Oto-Laryngology; Association of Military Surgeons of the United States, and was associate editor of the American Journal of Ophthalmology. Dr. Fryer was a surgeon of skill and judgment and a student of medical science of rare acumen and originality, and his death is deplored by his many friends, both in and out of the profession.

Joseph Thatcher Woods, M.D. University of Michigan, Ann Arbor, 1855; major-surgeon of the second division, Twenty-Third Corps, United States Volunteers, during the Civil War; thereafter for several terms health officer of Toledo and a member of the faculty of Toledo Medical College and Western Reserve University, Cleveland, and a member of the surgical staffs of St. Vincent's and the Toledo Hospital; died at the home of his sister in Washington, D. C., August 5, aged 84.

Stephen Pierson, M.D. College of Physicians and Surgeons, New York City, 1869; a member of the American Medical Association and New York Academy of Medicine; surgeon to All Souls and Memorial hospitals, Morristown, N. J.; a veteran of the Civil War; president of the Morristown Board of Education and vice-president of the Washington Association of New Jersey; died at his home in Morristown, August 10, from heart disease, aged 66.

James A. Lewis, M.D. New York University, New York City, 1869; for many years a practitioner of South Buffalo, N. Y.; formerly health commissioner of Lockport, N. Y., and president of the Lockport Tuberculosis Committee; for five years in charge of a hospital at West Seneca, N. Y.; died at his home in Lockport, August 3, from hemorrhage of the stomach, aged 63.

John Chapman Davie, M.D. University of California, San Francisco, 1865; premier and attorney general of Vancouvers Island while it was a crown colony, and later governor and premier of British Columbia; one of the oldest and most eminent surgeons on the Pacific Coast; died at Oak Bay, August 10, from tuberculosis, aged 67.

Albert Steinrauf, M.D. Barnes Medical College, St. Louis, Mo., 1898; ever since his graduation in the United States employ in the Philippine Islands, and for the last six years of the Canal Zone; died at the home of his parents in St. Charles, Mo., August 5, from tropical disease of the liver, aged 33.

William Hope Davis, M.D. Eclectic Medical Institute, Cincinnati, 1865; a veteran of the Civil War; two terms secretary of National Eclectic Association; for many years a practitioner of Springfield, Ill.; died at his home in San Antonio, Texas, August 5, aged 73.

George W. Sayles, M.D. University of Buffalo, N. Y., 1894; a member of the Erie Railway Surgeons' Association and local surgeon of the Erie, New York Central and West Shore railroads; died at his home in Buffalo, August 6, from tuberculosis, aged 44.

George H. Fox, M.D. Castleton (Vt.) Medical College, 1851; a member of the Vermont State Medical Society and one of the founders of the Rutland Medical Club; died at his home in Rutland, July 28, from disease of the intestines, aged 81.

J. [illegible] Smith, M.D. University of Louisville (Ky.), [illegible] ber of the American Public Health Association; [illegible] years a practitioner of Denver; died in Excelsior [illegible], August 3, from nephritis, aged 60.

[illegible] Doull Sinclair, M.D. Harvard Medical School, [illegible] formerly of Boston and later a practitioner of Kiel, Germany, and since his retirement a resident of Florence, Italy; died at his home in that city, August 7.

Thomas D. Williams, M.D. University of Pennsylvania, Philadelphia, 1885; for several years local surgeon to the Pennsylvania Railroad at Jersey City; died at his home, August 4, from ptomaine poisoning, aged 55.

Elbridge A. Thompson, M.D. Castleton (Vt.) Medical College, 1852; of Dover, Maine; formerly a member of the state legislature; died suddenly at Isle of Springs, Maine, August 2, from heart disease, aged 84.

Nathan Johnson Davis, M.D. Harvard Medical School, 1871; died at his home in East Somerville, Mass., where he has practiced for more than forty years, August 8, from heart disease, aged 67.

John Garfield (license, Massachusetts, years of practice, 1894); for more than forty years a practitioner of Malden; died at the home of his daughter in Everett, Mass., August 5, aged 76.

Walter W. Lester, M.D. Louisville (Ky.) Medical College, 1892; a member of the Kentucky State Medical Association; died at his home in Paintsville, Ky., August 7, from typhoid fever.

Warren W. Drake (license, Ohio, years of practice, 1896); for forty-eight years a practitioner of the state; died at his home in Findlay, August 6, from cerebral hemorrhage, aged 70.

Oliver H. Babcock, M.D. University of Buffalo, N. Y., 1861; for nearly half a century a practitioner of Hammondsport, N. Y.; died at his home in that city, July 29, aged 77.

Worthington W. Hopkins, M.D. University of Maryland, Baltimore, 1858; died at his home in Gover's Hill, near Havre-de-Grace, Md., August 4, aged about 74.

Brayton Muscott, M.D. University of California, San Francisco, 1896; of Friday Harbor, Wash., was accidentally shot and killed, August 6, aged 39.

Charles Eddy, M.D. Bellevue Hospital Medical College, 1873; died at his home in Brooklyn, August 10, aged 62.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

TABLET MEDICATION AND THE PUBLIC

There is no denying the fact that the tablet form of medication has manifest advantages; its convenience and accuracy are alone sufficient insurance that it has come to stay. But these advantages are also potent for much harm, in that they appeal to the non-medical no less than to the medical man, and thus become a great inducement to self-medication. The man who wishes to be his own physician is especially well satisfied with a preparation which calls for no prescription, but can be obtained at the drug-store and taken without the need of glass or spoon. Many tablet manufacturers stamp their initials on their tablets, or make them of a distinctive color or shape; this is done, so they say, to prevent substitution on the part of dishonest pharmacists. While firms may be justified in protecting their interests by adopting a general mark or device to identify tablets of their make, there is no justification for the plan followed by some of giving a particular shape or a particular color to each combination. Such a device can have but one object in view, namely, to bring prominently before the patient the individuality of the medicine he is taking. That this may lead the patient to injure himself or others by the careless use of highly poisonous drugs goes without saying.

Our attention has been called recently to a particularly dangerous form of advertising. A firm has put on the market a bichlorid of mercury tablet, each tablet containing 7½ grains of mercuric chlorid and these are sold under the catchy name "Clover Antiseptic Tablets." Not only are these tablets sold under an innocent-sounding title, but the public safety is still further disregarded by their being made in the shape of a clover leaf. The good fortune supposed to attend the clover leaf would not only prove attractive, but would also lessen the sense of danger because of the supposed harmlessness of vegetable remedies.

The abuse of the corrosive sublimate tablet has borne bitter fruit in accidental poisoning by the use of this substance under the titles of antiseptic tablets, disks, wafers, etc. There is much to be regretted by both the physician and the pharmacist in the history of the employment of mercuric chlorid. The day of its indiscriminate use by the medical profession has long passed, but the knowledge gained by the public from tablets inadvertently placed in their hands by physicians or recommended by druggists has led to their use, especially for the prevention of conception, with disastrous results. Several cases have recently come to notice in which the victim or her consort placed the undissolved tablet in the vagina with fatal effect.[1] The use by the public of such tablets in vaginal douches for the same purpose has been the cause of death[2] in several cases.

In the interest of public safety, physicians should do their utmost to discourage the indiscriminate use of corrosive sublimate tablets. They should particularly avoid those which, because of their non-descriptive, catchy title or distinctive shape are liable to be used by those ignorant of their dangers.

LAY APPRECIATION OF EXPOSURE OF MEDICAL FRAUDS

The Poughkeepsie (N. Y.) *Eagle* comments editorially as follows: "The American Medical Association is doing good work by giving extra publicity to the exposures of fake cures that have been made and clinched through prosecution by the government for fraudulent use of the mails. This publicity is not only through The Journal of the Association, but stories of some of the more notorious frauds are published in pamphlet form. 'The Rupert Wells Cancer Cure Fraud' is the latest of these we have seen. The story of how such quack remedies deceive hundreds of ignorant people, and some of fair intelligence, is not without touches of human interest, and seems to us to show that here is a department where more government supervision and regulation would benefit many people."

"NEW REMEDY" STAGNATION

An article by Professor Biderfeld in the *Deutsche medizinische Wochenschrift*, June 22, 1911, p. 1153, on the remedies introduced during the last year, begins by discussing the dearth of new discoveries in medicines. The author recalls that in an article published last year he stated that stagnation in the discovery of new remedies was a characteristic of the present time. This stagnation becomes apparent by the substitution for remedies based on really new ideas, medicaments elaborated by slight variations of old ideas or even of mixtures of well-known remedies. The author further notes that the same conditions have prevailed during the past year. That this stagnation is felt seriously in Germany is shown further by an advertisement which appears in another German medical weekly in which it is stated that a large firm will pay physicians for ideas suggesting new forms of medication. No alarm need be felt at this dearth of inventiveness, as we feel sure the medical profession will be benefited by a respite from the flood of new synthetics and will grasp the opportunity thus afforded for a closer study of those now on the market.

Austin Flint's Notes on a Consumptive

To the Editor:—In going over the records of the late Dr. Austin Flint, New York, I happened on the following report of a case of pulmonary tuberculosis, together with Dr. Flint's notes.

Case Pulmonary Tuberculosis. Circumstances Illustrating Diagnosis Before Ulceration Has Ensued

A young man, aged 25, applied to me to-day for a cough. He has been in the habit of going on the lake in the summer seasons. At present he is tending a recess. His habits are good, but occasionally he takes a little spirit. I mean that he is not intemperate. Beyond this I did not inquire. His name is George Fowler. Is not aware that his family are prone to consumption. [They are not.] His father is still living. As this case illustrates the value of circumstances bearing on diagnosis in obscure cases of pulmo-tuberculosis before ulceration, I will note precisely its important points for after-reference.

His cough has existed *all* winter and he has not before applied for medical advice. [Phthisis rarely creates alarm.] It did not follow any acute attack of bronchitis or any other pulmonary inflammation. Thinks he must have taken cold, but this is a matter of course.

His cough has not been severe, has created no pain and never occurs inde[illegible] [This shows that in this case, if the[illegible] of the tuberculous deposit does not ex[illegible]ough. It is only the presence of the [illegible]bes.]

He expectorates moderately, but especially in the morning, and represents it as sometimes yellow, and sometimes of a darker color, probably ink color. [It strikes me here is a point of some import: if the case were one of bronchitis purely (which it is if it be not tuberculous) there would be greater secretion through the day, because the mucous membrane would be more irritated by inhaling dust, etc. Another and much stronger point, moreover, is that the cough and expectoration are both too little for a chronic bronchitis.]

He has at various times had shooting pains in different portions of chest. [Slight pleuritic adhesions. This is very different from the soreness of bronchitis, which would also be more or less constant if it existed at all.]

He has had very frequently chilly sensations, especially shooting down the back and into the shoulders. Is subject to them almost daily. Attributes this to having formerly had the fever and ague. [A symptom of considerable value.] Has lost considerable flesh during the winter. [Another bad symptom.] Is readily put out of breath by exercise. [Another significant fact.] Has lost some strength, but thinks not much. [He has probably lost more than he thinks.] Appetite is good. Bowels are regular. Sleeps well and feels well. Digests well for aught that he knows.

Pulse is 100. I saw him last night and to-day. It enumerated this last night and was not less this morning. [A very bad symptom. One of the most reliable of rational facts. He had indubitably tuberculous fever. With the same accelerated circulation from any other cause—from local inflammation he would be more conscious

Marriages

Charles Martin Strotz, M.D., Philadelphia, to Miss Estella Erwin of McVeytown, Pa., at Cristobal, Canal Zone, August 2.

Burt D. Harrington, M.D., Flatbush, L. I., to Mrs. Florence Omlsted Randall of Hackensack, N. J., August 2.

Arnold Burkelman, M.D., to Mrs. Mary J. Lindsay Schallert, both of Los Angeles, Cal., August 17.

Edwin Holland Trower, M.D., to Miss Catherine Elizabeth Rush, both of Eastville, Va., June 28.

James N. Shearl, M.D., Middletown, Ill., to Miss Bertha M. Nicholson of Tower Hill, Ill., August 2.

Ira Stanley Pope, M.D., Chevy Chase, Md., to Miss Marie M. Spatola of Philadelphia, August 9.

James Edward Allgood, M.D., Liberty, S. C., to Miss Ruth Thompson of Inman, S. C., June 20.

Elisha B. Jackson, M.D., to Mrs. Lydia Ward-Hubbard, both of Aberdeen, S. Dak., July 31.

James M. Delevett, M.D., Baltimore, to Miss Mary E. Fitzhugh at Philadelphia, August 9.

Fred C. Jordan, M.D., Lewis, Iowa, to Miss Berma Bland of Des Moines, August 2.

Deaths

Alvin Allace Hubbell, M.D. University of Buffalo (N. Y.), 1876; one of the most prominent specialists on diseases of the eye of western New York and a prolific writer, died in Buffalo, August 10, of general arteriosclerosis, aged 65. After graduating with honors from the University of Buffalo, he studied diseases of eye under the late Dr. Samuel D. Gross in Philadelphia for more than a year, and then began his practice in that specialty in Buffalo; his ability was at once recognized and his practice rapidly increased. After his graduation Dr. Hubbell was made professor of ophthalmology in the Niagara University, Buffalo. In 1898, when this institution became consolidated with the University of Buffalo, he became professor of the same specialty in the latter school, and in the spring of 1911 he was made emeritus professor of ophthalmology. For several years Dr. Hubbell was surgeon to the Charity Eye, Ear, Nose and Throat Hospital, the Sisters of Charity and the Erie County Hospital. He was also oculist to the Lake Shore and Michigan Southern Railroad. He was a member of the American Medical Association, chairman of the Section on [illegible]; one of the founders of the [illegible] Club; president in 1908 of the [illegible] Society and a member of the American Academy of Ophthalmology and Oto-Laryngology. He was the author of a number of articles bearing on his specialty, and in 1908 published a volume entitled "The Complete History and Development of Ophthalmology from 1800 to 1870."

Blencowe E. Fryer, M.D. University of Pennsylvania, Philadelphia, 1859; colonel, medical corps, U. S. Army, retired; one of the most prominent ophthalmologists of the southwest; died at Marquette, Mich., August 13. At the outbreak of the Civil War, Dr. Fryer entered the Army as assistant surgeon and passed through the successive grades to lieutenant colonel before his retirement in 1891, and received his promotion to colonel retired in 1904. While he was stationed at Fort Leavenworth, Kan., Major Fryer was called to the chair of ophthalmology in Kansas City Medical College, and was made permanent professor of that branch ten years later, and thereafter confined his medical work to diseases of the eye and ear. He was a member of the American Academy of Medicine, American Ophthalmological Society, American Academy of Ophthalmology and Oto-Laryngology; Association of Military Surgeons of the United States, and was associate editor of the American Journal of Ophthalmology. Dr. Fryer was a surgeon of skill and judgment and a student of medical science of rare acumen and originality, and his death is deplored by his many friends, both in and out of the profession.

Joseph Thatcher Woods, M.D. University of Michigan, Ann Arbor, 1855; major-surgeon of the second division, Twenty-Third Corps, United States Volunteers, during the Civil War; thereafter for several terms health officer of Toledo and a member of the faculty of Toledo Medical College and Western Reserve University, Cleveland, and a member of the surgical staffs of St. Vincent's and the Toledo Hospital; died at the home of his sister in Washington, D. C., August 5, aged 84.

Stephen Pierson, M.D. College of Physicians and Surgeons, New York City, 1869; a member of the American Medical Association and New York Academy of Medicine; surgeon to All Souls and Memorial hospitals, Morristown, N. J.; a veteran of the Civil War; president of the Morristown Board of Education and vice-president of the Washington Association of New Jersey; died at his home in Morristown, August 10, from heart disease, aged 66.

James A. Lewis, M.D. New York University, New York City, 1869; for many years a practitioner of South Buffalo, N. Y.; formerly health commissioner of Lockport, N. Y., and president of the Lockport Tuberculosis Committee; for five years in charge of a hospital at West Seneca, N. Y.; died at his home in Lockport, August 3, from hemorrhage of the stomach, aged 63.

John Chapman Davie, M.D. University of California, San Francisco, 1865; premier and attorney general of Vancouvers Island while it was a crown colony, and later governor and premier of British Columbia; one of the oldest and most eminent surgeons on the Pacific Coast; died at Oak Bay, August 10, from tuberculosis, aged 67.

Albert Steinrauf, M.D. Barnes Medical College, St. Louis, Mo., 1898; ever since his graduation in the United States employ in the Philippine Islands, and for the last six years of the Canal Zone; died at the home of his parents in St. Charles, Mo., August 5, from tropical disease of the liver, aged 33.

William Hope Davis, M.D. Eclectic Medical Institute, Cincinnati, 1865; a veteran of the Civil War; two terms secretary of National Eclectic Association; for many years a practitioner of Springfield, Ill.; died at his home in San Antonio, Texas, August 5, aged 73.

George W. Sayles, M.D. University of Buffalo, N. Y., 1894; a member of the Erie Railway Surgeons' Association and local surgeon of the Erie, New York Central and West Shore railroads; died at his home in Buffalo, August 6, from tuberculosis, aged 44.

George H. Fox, M.D. Castleton (Vt.) Medical College, 1851; a member of the Vermont State Medical Society and one of the founders of the Rutland Medical Club; died at his home in Rutland, July 28, from disease of the intestines, aged 81.

J. Solomon Smith, M.D. University of Louisville (Ky.), 1880; a member of the American Public Health Association; for thirty years a practitioner of Denver; died in Excelsior Springs, Mo. August 3, from nephritis, aged 60.

Alexander Doull Sinclair, M.D. Harvard Medical School, 1867, formerly of Boston and later a practitioner of Kiel, Germany, and since his retirement a resident of Florence, Italy; died at his home in that city, August 7.

Thomas D. Williams, M.D. University of Pennsylvania, Philadelphia, 1885; for several years local surgeon to the Pennsylvania Railroad at Jersey City; died at his home, August 4, from ptomaine poisoning, aged 55.

Elbridge A. Thompson, M.D. Castleton (Vt.) Medical College, 1852; of Dover, Maine; formerly a member of the state legislature; died suddenly at Isle of Springs, Maine, August 2, from heart disease, aged 84.

Nathan Johnson Davis, M.D. Harvard Medical School, 1871; died at his home in East Somerville, Mass., where he has practiced for more than forty years, August 8, from heart disease, aged 67.

John Garfield (license, Massachusetts, years of practice, 1894); for more than forty years a practitioner of Malden; died at the home of his daughter in Everett, Mass., August 5, aged 76.

Walter W. Lester, M.D. Louisville (Ky.) Medical College, 1892; a member of the Kentucky State Medical Association; died at his home in Paintsville, Ky., August 7, from typhoid fever.

Warren W. Drake (license, Ohio, years of practice, 1896); for forty-eight years a practitioner of the state; died at his home in Findlay, August 6, from cerebral hemorrhage, aged 70.

Oliver H. Babcock, M.D. University of Buffalo, N. Y., 1861; for nearly half a century a practitioner of Hammondsport, N. Y.; died at his home in that city, July 29, aged 77.

Worthington W. Hopkins, M.D. University of Maryland, Baltimore, 1858; died at his home in Gover's Hill, near Havre-de-Grace, Md., August 4, aged about 74.

Brayton Muscott, M.D. University of California, San Francisco, 1896; of Friday Harbor, Wash., was accidentally shot and killed, August 6, aged 39.

Charles Eddy, M.D. Bellevue Hospital Medical College, 1873; died at his home in Brooklyn, August 10, aged 62.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

TABLET MEDICATION AND THE PUBLIC

There is no denying the fact that the tablet form of medication has manifest advantages; its convenience and accuracy are alone sufficient insurance that it has come to stay. But these advantages are also potent for much harm, in that they appeal to the non-medical no less than to the medical man, and thus become a great inducement to self-medication. The man who wishes to be his own physician is especially well satisfied with a preparation which calls for no prescription, but can be obtained at the drug-store and taken without the need of glass or spoon. Many tablet manufacturers stamp their initials on their tablets, or make them of a distinctive color or shape; this is done, so they say, to prevent substitution on the part of dishonest pharmacists. While firms may be justified in protecting their interests by adopting a general mark or device to identify tablets of their make, there is no justification for the plan followed by some of giving a particular shape or a particular color to each combination. Such a device can have but one object in view, namely, to bring prominently before the patient the individuality of the medicine he is taking. That this may lead the patient to injure himself or others by the careless use of highly poisonous drugs goes without saying.

Our attention has been called recently to a particularly dangerous form of advertising. A firm has put on the market a bichlorid of mercury tablet, each tablet containing 7½ grains of mercuric chlorid and these are sold under the catchy name "Clover Antiseptic Tablets." Not only are these tablets sold under an innocent-sounding title, but the public safety is still further disregarded by their being made in the shape of a clover leaf. The good fortune supposed to attend the clover leaf would not only prove attractive, but would also lessen the sense of danger because of the supposed harmlessness of vegetable remedies.

The abuse of the corrosive sublimate tablet has borne bitter fruit in accidental poisoning by the use of this substance under the titles of antiseptic tablets, disks, wafers, etc. There is much to be regretted by both the physician and the pharmacist in the history of the employment of mercuric chlorid. The day of its indiscriminate use by the medical profession has long passed, but the knowledge gained by the public from tablets inadvertently placed in their hands by physicians or recommended by druggists has led to their use, especially for the prevention of conception, with disastrous results. Several cases have recently come to notice in which the victim or her consort placed the undissolved tablet in the vagina with fatal effect.[1] The use by the public of such tablets in vaginal douches for the same purpose has been the cause of death[2] in several cases.

In the interest of public safety, physicians should do their utmost to discourage the indiscriminate use of corrosive sublimate tablets. They should particularly avoid those which, because of their non-descriptive, catchy title or distinctive shape are liable to be used by those ignorant of their dangers.

LAY APPRECIATION OF EXPOSURE OF MEDICAL FRAUDS

The Poughkeepsie (N. Y.) *Eagle* comments editorially as follows: "The American Medical Association is doing good work by giving extra publicity to the exposures of fake cures that have been made and clinched through prosecution by the government for fraudulent use of the mails. This publicity is not only through The Journal of the Association, but stories of some of the more notorious frauds are published in pamphlet form. 'The Rupert Wells Cancer Cure Fraud' is the latest of these we have seen. The story of how such quack remedies deceive hundreds of ignorant people, and some of fair intelligence, is not without touches of human interest, and seems to us to show that here is a department where more government supervision and regulation would benefit many people."

"NEW REMEDY" STAGNATION

An article by Professor Biderfeld in the *Deutsche medizinische Wochenschrift*, June 22, 1911, p. 1153, on the remedies introduced during the last year, begins by discussing the dearth of new discoveries in medicines. The author recalls that in an article published last year he stated that stagnation in the discovery of new remedies was a characteristic of the present time. This stagnation becomes apparent by the substitution for remedies based on really new ideas, medicaments elaborated by slight variations of old ideas or even of mixtures of well-known remedies. The author further notes that the same conditions have prevailed during the past year. That this stagnation is felt seriously in Germany is shown further by an advertisement which appears in another German medical weekly in which it is stated that a large firm will pay physicians for ideas suggesting new forms of medication. No alarm need be felt at this dearth of inventiveness, as we feel sure the medical profession will be benefited by a respite from the flood of new synthetics and will grasp the opportunity thus afforded for a closer study of those now on the market.

Austin Flint's Notes on a Consumptive

To the Editor:—In going over the records of the late Dr. Austin Flint, New York, I happened on the following report of a case of pulmonary tuberculosis, together with Dr. Flint's notes.

Case Pulmonary Tuberculosis. Circumstances Illustrating Diagnosis Before Ulceration Has Ensued

A young man, aged 25, applied to me to-day for a cough. He has been in the habit of going on the lake in the summer seasons. At present he is tending a recess. His habits are good, but occasionally he takes a little spirit. I mean that he is not intemperate. Beyond this I did not inquire. His name is George Fowler. Is not aware that his family are prone to consumption. [They are not.] His father is still living. As this case illustrates the value of circumstances bearing on diagnosis in obscure cases of pulmotuberculosis before ulceration, I will note precisely its important points for after-reference.

His cough has existed all winter and he has not before applied for medical advice. [Phthisis rarely creates alarm.] It did not follow any acute attack of bronchitis or any other pulmonary inflammation. Thinks he must have taken cold, but this is a matter of course.

His cough has not been severe, has created no pain and never occurs independently of expectoration. [This shows that in this case, if there be tubercles, the presence of the tuberculous deposit does not excite irritation sufficient for cough. It is only the presence of the secretion in the bronchial tubes.]

He expectorates moderately, but especially in the morning, and represents it as sometimes yellow, and sometimes of a darker color, probably ink color. [It strikes me here is a point of some import; if the case were one of bronchitis purely (which it is if it be not tuberculous) there would be greater secretion through the day, because the mucous membrane would be more irritated by inhaling dust, etc. Another and much stronger point, moreover, is that the cough and expectoration are both too little for a chronic bronchitis.]

He has at various times had shooting pains in different portions of chest. [Slight pleuritic adhesions. This is very different from the soreness of bronchitis, which would also be more or less constant if it existed at all.]

He has had very frequently chilly sensations, especially shooting down the back and into the shoulders. Is subject to them almost daily. Attributes this to having *formerly* had the fever and ague. [A symptom of considerable value.] Has lost considerable flesh during the winter. [Another bad symptom.] Is readily put out of breath by exercise. [Another significant fact.] Has lost some strength, but thinks not much. [He has probably lost more than he thinks.] Appetite is good. Bowels are regular. Sleeps well and feels well. Digests well for aught that he knows.

Pulse is 100. I saw him last night and to-day. It enumerated this last night and was not less this morning. [A very bad symptom. One of the most reliable of rational facts. He had indubitably tuberculous fever. With the same accelerated circulation from any other cause—from local inflammation he would be more conscious of severe ailment. He would be confined to his bed or at least to his house. On the contrary, he is now about his business. If the disease were chronic bronchitis he would not have this pulse.]

---

[1] The Journal A. M. A., April 9, 1911, pp. 1203 and 1459.

[2] The Journal A. M. A., April 30, 1910, pp. 1459, 1867; also Am. Jour. Obst., March, 1911, p. 473.

Says he has no fever at night; hands and feet are not hot. Does not perspire. [He has tuberculous fever, not yet hectic fever.]

Here is a general view of the rational symptoms. Now of the physical. There is evidently a slight dulness on the left side con*trasted with the right. I think there is slight dulness on the right* also. I think the respiration is rough on both sides and there is an evident distinction between the two sides—the left being more rough. This distinction was particularly perceptible posteriorly in the interscapular spaces. Action of heart unusually perceptible to the ear, in all parts of chest. On the left side there is a slight hitch in the respiratory murmur. No râles were perceptible.

In view of the foregoing history I consider it demonstrative that this young man is the victim of tuberculous disease of lungs. His symptoms will progressively increase, he will shortly have hectic fever, judging especially from the tuberculous fever, I predict that he will succumb within six months, and very likely within three.

Mark that he is not now in his own opinion an invalid. He is merely troubled with a slight cough. He has no apprehensions. He has no cavities, no hectic—and yet he may confidently be pro*nounced a doomed man. If the result confirm this prediction it* will certainly show that attention to the points connected with the diagnosis of pulmonary tuberculosis enables the practitioner to have a prescience which must appear remarkable to one not acquainted with the value of evidence bearing on the subject.

April 10, 1846.

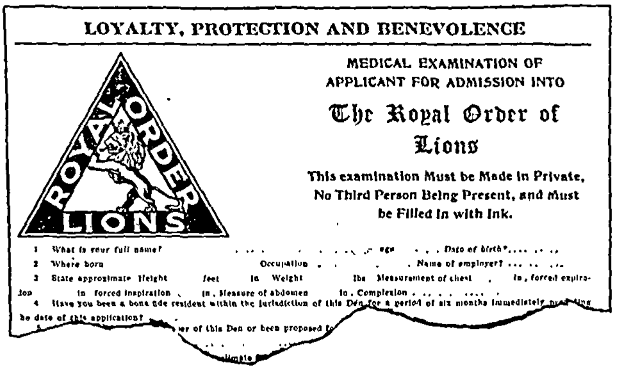
Oct. 11, 1846. This person went to Iowa and passed the summer. He returned recently and again applied to me for advice. His cough and other symptoms were about the same as they were last April. He had lost little if any flesh. Had taken no medicine. I did not examine him closely, but I could not discover on a general examination that the disease had made any appreciable progress. Dr. Trowbridge, Sr., saw him with me, concluded in the diagnosis of incipient tuberculosis and joined in advice to seek a warm climate for the winter. The patient has taken our advice, but his particular destination I do not know. He promised to write.

That Dr. Flint should have grasped so clearly the diagnostic significance of the various symptoms and signs of tuberculosis as early as 1846, shows the acuteness of his diagnostic ability. It seems worth while to publish this case from a historical point.

Lawrason Brown, Saranac Lake, N. Y.

The Royal Order of Lions Fraud

To the Editor:—There is a fellow traveling over the country inducing the physicians to examine for his new order the "Royal Order of Lions" so called. He calls on two physicians in each city to obtain their services as examiners. For this privilege they pay $5.00 in advance. He gives you a receipt, bids you goodbye and that is the last you hear from him. He has roped in any number of doctors throughout Minnesota. There is no such order in existence so far as we can learn. Enclosed find blank application and receipt. He is of slight build, dark complexion, medium height, traveling with a woman whom he calls his wife; she is a dark, short, robust, pretty-faced girl. I thought a notice could be published in the next issue which might be the means of catching him somewhere.



LOYALTY, PROTECTION AND BENEVOLENCE

MEDICAL EXAMINATION OF
APPLICANT FOR ADMISSION INTO

The Royal Order of
Lions

This examination Must be Made in Private,
No Third Person Being Present, and Must
be Filled in with Ink.

1 What is your full name? . . . . age . . . Date of birth? . . . . . .
2 Where born Occupation . . . . Name of employer? . . . . . .
3 State approximate Height feet in Weight lbs Measurement of chest , in , forced expiration in forced inspiration , in , Measure of abdomen in , Complexion . . . .
4 Have you been a bona fide resident within the jurisdiction of this Den for a period of six months immediately preceding the date of this application?

Photographic reproduction (reduced) of part of the medical examination and application blank used by the individual who persuaded physicians to pay $5 for the privilege of becoming a medical examiner for the hypothetical Royal Order of Lions.

Charles F. Brigham, St. Cloud, Minn.
President St. Cloud Board of Health.

Comment.—The application blank, receipt and other printed matter which Dr. Brigham sends with his letter have nothing on them to show where the headquarters of the Royal Order of Lions are located. The "Receipt and Admittance Card, Supreme Den of the World, Royal Order of Lions" has the name "J. L. Giblin, National Organizer" printed on it and the receipt is signed "J. R. Landauer, Supreme Organizer." The latter name also appears on some of the printed matter that details the wonderful advantages to be gained by joining "The Fastest Growing, Fraternal, Social and Beneficial Order." The descriptive pamphlet states that this is "The Order That Does Things;" Dr. Brigham's letter indicates that it evidently does.

Fetal Death from Knotted Cord

To the Editor:—In The Journal, August 12, page 563, Dr. Froehlich reports a case of death of fetus due to twisting of the cord. In a somewhat similar case under my care, labor occurring on the date expected, the patient had not felt life for six days. Physical examination revealed absence of heart sounds. A fully developed male child was born dead. There was a knot in the cord about 6 inches from the fetal end, drawn tightly enough to cut off the circulation completely.

Mark Beach, M.D., Clinton, Kan.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DIAGNOSIS OF A CASE OF NARCOLEPSY

To the Editor:—I have a somewhat baffling case under my care, and in view of the fact that the text-books, so far as I have investigated, suggest very little on the subject, I appeal to you. History: The patient is a married woman, under middle age, the mother of two healthy children. Her pregnancies have been very easy; she is of *medium height* and weight, is intelligent and looks the picture of good health and says she feels it, with the exception of some sharp pains of an anginal character over the pericardium, from which at intervals she is free. She came to North Dakota about ten years ago and began almost at once to experience great drowsiness. She would rest her arm on the table, for example, at meal-time and fall into a profound sleep, from which she would be aroused with considerable effort. To prevent a further lapse it would be necessary for her husband to walk with her in the cold air. At this time, and for some years back, she would lapse into a sound sleep, even while at the table, when chatting with friends or while holding the baby. When carrying her baby she had to be watched in order to be prevented from dropping it. When she felt the attack coming on while at her meal she would hurriedly sip a little tea from her cup, but often she would begin to snore while the cup was half way between the table *and her lips. The sleep is profound, lasts only* a few minutes, after which the patient wakes perfectly refreshed and clear. Objective findings: Urinalysis is negative; the chest and abdominal organs are normal; the vision is good; the pupils are equal in size and active to light and accommodation; no focal symptoms of intracranial tumor or epilepsy are present. As the condition is very perplexing I should greatly appreciate advice.

M. L. G.

Answer.—The case appears to belong to that rare and interesting, though obscure, condition called "narcolepsy," which Gélineau first described in the *Gazette des Hôpitaux*, 1880, p. 626. In the *Archives Gén. de Médecine*, 1905, No. 25, Raymond succinctly defines true narcolepsy as a condition characterized by a sudden and irresistible inclination to sleep, occurring during the hours not usually spent in normal sleep and appearing at irregular intervals, lasting a variable period of time. The person so affected may be overpowered by sleep in the midst of his ordinary occupation and at most unexpected moments, even during meals at table. Authorities still differ in respect to the proper place of narcolepsy in the classification of diseases. All agree in calling it a functional neurosis when it is not symptomatic of brain tumor, syphilis or autointoxication. Although Gélineau described narcolepsy as an independent neurosis, most neurologists agree with Féré ("Twentieth Century Practice of Medicine," p. 501-503), who classes it among the symptoms of hysteria. In speaking of sleeping attacks, he says among other things: "In hysterical subjects we sometimes observe sudden but short-timed attacks of deep slumber, which Gélineau has designated by the name of narcolepsy, but which are always symptomatic, as Ballet has well shown." Continuing, Féré compares these crises to postepileptic stertor, but he regards them as larval forms of hystero-epilepsy, which is true hysteria, according to our latest conceptions of this symptom-complex. In conclusion, he quotes Pitres as having reported the case of a woman who had to yield to the sleeping attack even when she ran about trying to prevent it, or when she placed herself under a shower-bath. In opposition to this view, it must be stated that neurologists of experience see cases in which a short, sudden attack of drowsiness constitutes the sole symptom of petit mal in idiopathic epilepsy. If there be no obesity, diabetes, gout or hepatic disorder, and if tumor or syphilis of the brain can be excluded, and further, if there are *no other* evidences of hysteria, the condition should awaken a strong suspicion of epilepsy of the petit mal variety. The treatment of true narcolepsy is extremely unsatisfactory. If after a most painstaking examination we are convinced that there is no organic or metabolic disorder present, we resort to all those measures advised to combat hysteria. A course of thorough purging may cause a temporary disappearance of the tendency to sleep-attacks. Further, attention to proper hygiene and environmental changes and psychotherapy may be tried. Last of all, if these measures are of no avail, a course of bromids, as for ordinary epilepsy, should be given a faithful trial.

Besides the authorities mentioned, there will be found in the *American Journal of the Medical Sciences* for August, 1906, an interesting report on a case of narcolepsy, by Albert N. Blodgett, who traces the condition in his case to a faulty heredity, extending over several generations.

HYPODERMIC INJECTIONS OF EUCALYPTUS OIL IN TUBERCULOSIS

To the Editor:—Please give references and a review of the literature on the use of oil of eucalyptus by hypodermic injection in tuberculosis. J. A. BURNETT, M.D., Marble City, Okla.

ANSWER.—The following articles have appeared in recent years:

Berliner, M.: Zur Behandlung der Tuberkulose, Deutsche klin-therap. Wchnschr., Nr. 17, 1906.

Blüm [illegible] erculosis with Eucalyptus Oil Injections, [illegible] Tuberkulose, B. viii, H. 2. Abstr. in THE [illegible] p. 1960.

Berliner, M.: Treatment of Tuberculosis with Injections of Eucalyptol, Beiträge zur Klinik der Tuberkulose, B. x, H. 3.

This treatment of tuberculosis has been recommended by Berliner who gives it by hypodermic injections of a solution in castor oil. He begins with a somewhat weak solution, but increases until the dose reaches 2 c.c. of a 33⅓ per cent. solution twice a week. His results, he claims, are unusually favorable. Cough, he says, becomes less troublesome or disappears and the dyspnea is relieved. Blümel submitted the method of Berliner to a critical trial and reports unfavorably, and feels that it is his duty to warn against certain side-effects as dangerous and injurious, especially as to the method of application advocated. To this Berliner replies that the purity of the castor oil is very important and recommends a proprietary preparation made by a somewhat obscure German firm. Blümel found that patients complained of pain after the injections, but Berliner denies that that has been his experience. The objection of Blümel that the injections were followed by the appearance of albumin in the urine is not accepted by Berliner, who attributes this symptom to an antecedent disease of the kidney.

MILD TYPE OF SMALL-POX

To the Editor:—During the last few years there have been reported in the United States small-pox epidemics with remarkably low mortality. On account of this benignity, many physicians believed that these were not the real small-pox, and much discussion was aroused. Since last year we have had a similar epidemic here, and some physicians believed that we had to deal with a new disease, much like small-pox, but still different in many ways. I am very anxious to obtain information on the following points: 1. Has it been proved that the epidemics in the United States were true small-pox?

2. On what is this proof based?

A. CARINI, Director Pasteur Institute, Sao Paulo, Brazil.

ANSWER.—1. No serious doubt has been expressed about it in the last ten years. From the early months of 1899 to 1901, many physicians having little or no experience with small-pox were unable to make a diagnosis of the mild type of the disease at that time prevalent in the United States. A few health officers with little experience with this disease were doubtful about the diagnosis, but at no time were those of the health officers who had had experience with small-pox in doubt about the nature of the disease. Anyone who is at all familiar with the various types of small-pox could not hesitate for a moment to pronounce the disease under consideration small-pox. Cases of the disease under discussion from all parts of the United States, Canada and Mexico, where the mild and debatable disease existed, were clearly small-pox, though the death-rate was low.

From Jan. 1, 1899 to Dec. 31, 1902, 692 cases of small-pox were treated in the Chicago Isolation Hospital, with a death-rate of a fraction under 2 per cent. (1.78 per cent.). From Jan. 1, 1903, to Dec. 31, 1905, 1,293 cases were admitted to the hospital, with a death-rate of 10.5 per cent. From Jan. 1, 1906, to the present date (Aug. 8, 1911), 355 patients were admitted to the Isolation Hospital, of whom but three died and two of these were imported from Europe—a severe type of the disease.

2. The period of incubation is the same as that of small-pox. The three days of prodromal symptoms followed by a papular eruption and a drop in temperature are invariably present. The life history of the lesion is that of small-pox—papule, vesicle, pustule, scab, leaving pigmentation spots, though the course is sometimes short, like small-pox modified by an old vaccination, but all the symptoms are present if the diagnostician has the patience to secure all the symptoms, not forgetting that many patients will lie about their symptoms through fear of being sent to the hospital. The disease attacks only those not protected by vaccination. Those *recently vaccinated, say within ten years, or those vaccinated* and revaccinated, do not contract the disease. Those not vaccinated, when exposed to the disease almost invariably contract the disease. Confluent and hemorrhagic cases of small-pox were placed side by side with hundreds of these mild cases in unvaccinated subjects in the hospital wards, where exposure of the latter to the former was close and prolonged, *and in no instance did a second disease develop.*

Dr. Rawlings, house physician at the Isolation Hospital, vaccinated a series of 100 patients recovered from this disputed mild type of small-pox and failed to secure a vaccination on any of them, though none had previously been vaccinated.

Confluent and hemorrhagic small-pox are contracted from the mild cases of so-called "Cuban itch." This has repeatedly been observed. *An attack of the disease protects from small-pox;* it protects against vaccination; vaccination protects against the disease and the disease conveys to others the severe types of small-pox.

A symposium on the subject of small-pox was read at the meeting of the American Medical Association held at St. Paul, in 1901. The papers read were published during that year. After a full discussion of the subject, a resolution was passed declaring it to be the opinion of the Section on Practice of Medicine that the epidemic then prevalent and under discussion was small-pox.

CARBON-DIOXID SNOW—CALENTURA FEVER

To the Editor:—Please tell me through THE JOURNAL (1) what carbon-dioxid snow is, and (2) what calentura fever is. I cannot find a definition for either term.

S. C. BROADSTREET, Mount Pleasant, Texas.

ANSWER.—1. Carbon-dioxid snow is carbon dioxid in the solid form, in which it is obtained by allowing the liquefied gas to escape from a container in the form of a spray. The evaporation of some of the liquid takes heat from the rest so that it freezes in fine particles like snow. Carbon-dioxid snow can be collected in a cloth or piece of chamois skin, pressed together and molded into various shapes. The layer of gas which surrounds it prevents it from freezing the hand unless too great pressure be exerted. When it is applied to the skin, the intense cold produced by its evaporation freezes the skin and produces the desired caustic effect. See article by W. A. Pusey, THE JOURNAL, Oct. 19, 1907, p. 1354.

2. *Calentura* is Spanish for "heat" or "fever," and is applied to a mild ephemeral or continued fever of tropical countries, often called by the natives of the English-speaking tropics a "cold." The term is also applied to thermic fever or sun-stroke.

THE COMPOSITION OF HAIR DYES AND THE EFFECTS OF THEIR USE

To the Editor:—What reliable scientific information exists in regard to hair dyes? I am interested to find out what substances are employed, whence they come from, what injurious effects they may produce, etc. R. C.

ANSWER.—Hair dyes are chiefly of two classes. (1) Those which secure the effect by precipitating a metallic compound, usually sulphid of a reduced silver salt in the hair, and (2) those which darken the hair by the oxidation of some organic substances, such as pyrogallol. A number of combinations of the first class have been recommended in the past but they have largely fallen into disuse. Dyes of the second class are largely proprietary and depend on the use of various coal tar products which are likely to be irritating to the skin and may produce a severe dermatitis. Among the metallic compounds used for dyeing the hair may be mentioned salts of silver, lead, mercury, bismuth and iron. The salts of silver blacken on exposure to light or by the use of reducing agents. Silver may be absorbed by the scalp, but poisoning in this manner seems to be unusual. Lead is probably more frequently absorbed and it is possible that it may give rise to serious poisoning. The same may be said to be true of mercury. Of course, no such effects are likely to be produced by the salts of bismuth or iron. Systemic poisoning from hair dyes seems to be very rare and some dermatologists state that these substances are not known to have a deleterious effect on the general health. A considerable number of reports have appeared in The Journal of dermatitis, sometimes quite severe, which was attributed to the use of a proprietary hair dye, known as "Mrs. Potter's Walnut Stain." This dye (as well as another called "Eau Sublime") contains paraphenylene diamin which by the action of hydrogen dioxid gives quinone, a substance which has a very irritating action. The poisonous qualities of paraphenylene diamin have long been known. In addition to thirty-two cases of poisoning that have been reported to The Journal (Feb. 13, 1909; March 6, 1909; April 3, 1909; May 15, 1909; Aug. 14, 1909, and Sept. 4, 1909), eighteen cases have been reported by Gathelineau. Brocq described a severe form of poisoning due to this chemical; Balso reports a case of poisoning due to wearing hose which had been dyed with the chlorate of paraphenylene diamin, and Mewborn (The Journal A. M. A., May 18, 1901) reported a case of dermatitis from the use of a hair dye having this chemical for its base. This subject has also been discussed editorially in The Journal, Sept. 4, 1909, page 803.

PREPARATION OF SODIUM CACODYLATE SOLUTION FOR HYPODERMIC INJECTION

To the Editor:—Please give the formula for preparing sodium cacodylate solution as for hypodermic injection and the daily dose advised and your opinion as to its efficacy.

E. P. McGehee, Lake Village, Ark.

Answer.—Sodium cacodylate is readily soluble in water so that the desired dose, usually from ½ to 2 grains, can be given in an ordinary hypodermic syringe full of sterile water. Stock solutions should not be used, as they deteriorate readily, but the pharmacist should weigh out the desired dose for each administration and place it in a sterile bottle for use at the time of injection. Wholesale druggists furnish the drug in ampoules ready for use. J. B. Murphy advises an initial dose of from 2 to 4 grains, which should not be repeated within three or four days unless there are special indications for it. Other clinicians have given from ½ to 3 grains daily for a number of days. Probably it is better, as a rule, to allow an interval of three days. Clinical experience with sodium cacodylate in syphilis is not yet sufficiently extensive to enable a conclusive opinion regarding its efficacy to be formed.

MEDICAL WRITINGS OF OLIVER WENDELL HOLMES

To the Editor:—Kindly let me know through the "Queries and Minor Notes" column if the complete medical writings of Oliver Wendell Holmes are published in book form, and if so, by whom, the price, etc. Most of us have read extracts from Dr. Holmes' writings and the majority of us, perhaps, have a copy of his masterly paper on the infectious nature of puerperal sepsis filed away among our journals; but I, for one, should like to have such things in book form.

D. M. Molloy, Manila, P. I.

Answer.—The medical writings of Oliver Wendell Holmes have been published in one volume by Houghton, Mifflin & Co., Boston, under the title "Medical Essays." Price, $1.50.

The Public Service

Medical Department, U. S. Army

Changes during the week ended Aug. 12, 1911:

Boehs, Charles J., M.R.C., orders to Fort Porter, N. Y., for temporary duty revoked.

Ingalls, R. E., dental surgeon, left temporary duty at Fort Apache en route to Whipple Barracks, Ariz., for temporary duty.

Burket, John A., lieut., ordered to proceed from Fort Riley, Kan., to Fort Des Moines, Iowa, for temporary duty.

Moncrief, William H., captain, ordered to proceed from Fort Leavenworth, Kan., to Fort Sheridan, Ill., for duty with troops from post to Camp Perry, Ohio, and return to post instead of duty at Camp Port Huron, Mich.

Owen, Leartus J., captain, relieved from duty as inspector-instructor of the organized militia of Michigan, Aug. 9-18, 1911.

Blanchard, R. M., captain, detailed inspector-instructor, organized militia of Michigan, in camp Aug. 9 to 18, 1911, Port Huron, Mich.

Holmberg, Carl R., lieut., granted leave of absence for thirty days.

Wolven, F. Homer, dental surgeon, reported for temporary duty at Fort Gibbon, Alaska.

Winter, Francis A., major, will proceed to New York City for consultation with medical supply officer, in connection with purchase of medical supplies. On completion of duty to return to station.

Maus, L. Mervin, colonel, is granted leave of absence for one month and ten days on or about Aug. 21, 1911.

Gilchrist, Harry L., major, is detailed as instructor of sanitary troops at Camp Nevada, Mo., Aug. 20, 1911. On conclusion of encampment will return to his station.

Duncan, Louis C., captain, on arrival at San Francisco, will proceed to the Presidio and report to commanding officer, General Hospital, for duty.

Billingslea, Charles C., captain, when relieved by Captain Duncan, will proceed to Columbus Barracks, Ohio, for duty.

Phalen, James M., captain, is relieved Oct. 1, 1911, at Columbus Barracks, Ohio, and will proceed to New York City as attending surgeon.

Brewer, Isaac W., M.R.C., on arrival at San Francisco, will proceed to Fort Niagara, N. Y., for duty.

Smith, Herbert H., M.R.C., on his arrival at San Francisco, will proceed to Fort Lincoln, N. Dak., for duty.

Boards of officers to meet on September 1 for examination of applicants for acting dental surgeons are appointed as follows:

Fort Slocum, N. Y.: Wadhams, Sanford H., major; Boak S. Davis, dental surgeon; Tignor, Edwin P., dental surgeon.
Columbus Barracks, Ohio: Fisher, Henry C., lieut.-col.; Mason, George L., dental surgeon; Bernheim, Julien R., dental surgeon.
Jefferson Barracks, Mo.; Howard, Deane C., *major*; Voorhees, Hugh G., dental surgeon; McAlister, John A., dental surgeon.
Fort Logan, Colo.: Shook, Jay Ralph, major; Lauderdale, Clarence E., dental surgeon; Wing, Franklin F., dental surgeon.
Fort McDowell, Cal.: Brooks, William H., major; Hess, John H., dental surgeon; Chambers, William H., dental surgeon.

Truby, W. F., *major, granted two months' leave of absence.*

Kerr, Robert W., lieut., granted leave of absence for two months.

Marietta, S. U., M.R.C., ordered to active service and assigned to duty, Aug. 23, 1911, to Fort Sheridan, Ill.

Medical Corps, U. S. Navy

Changes for the week ended Aug. 12, 1911.

Taylor, J. L., P. A. surgeon, detached from the naval hospital, Norfolk, Va., and ordered to the naval hospital, Las Animas, Colo., for treatment.

Kelley, H. L., P. A. surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the Navy yard, Mare Island, Cal.

Hoyt, R. E., P. A. surgeon, detached from the Navy yard, Mare Island, Cal., and ordered to the Navy recruiting station, Los Angeles, Cal.

Bunker, C. W. O., P. A. surgeon, ordered to duty at the naval hospital, Mare Island, Cal.

Parham, J. C., asst.-surg., ordered to duty at the naval hospital, Philadelphia.

Zalesky, W. J., P. A. surgeon, detached from the *Franklin* and ordered to the Navy yard, Charleston, S. C.

Howard, J. V., P. A. surgeon, detached from the *Supply* and ordered to the naval station, Guam, P. I.

Abernathy, R. T., pharmacist, detached from the naval hospital, Las Animas, Colo., and ordered to the naval hospital, Washington, D. C., for observation and treatment.

Stuart, M. A., P. A. surgeon, detached from the Navy yard, Charleston, S. C., and ordered to the *Franklin*.

U. S. Public Health and Marine-Hospital Service

Changes for the week ended Aug. 9, 1911.

Trask, J. W., asst. surg.-gen., granted twenty-six days' leave of absence from Aug. 8, 1911.

Austin, H. W., surgeon, granted one day's leave of absence, Aug. 6, 1911, under paragraph 189, Service Regulations.

Williams, L. L., surgeon, granted three days' leave of absence from Aug. 6, 1911, under paragraph 189, Service Regulations.

Mathewson, H. S., P. A. surgeon, relieved from duty at Fort Stanton, N. Mex.

McMullen, John, P. A. surgeon, granted twenty-one days' leave of absence from Aug. 7, 1911.

Robinson, D. E., P. A. surgeon, granted twenty-one days' leave of absence from Aug. 12, 1911.

McLaughlin, A. J., P. A. surgeon, directed to proceed to Providence, R. I., from Boston, Mass., and on completion of duty enjoined to return to Boston.

Lloyd, B. J., P. A. surgeon, granted two days' leave of absence, July 28-29, 1911.

Rucker, W. C., P. A. surgeon, granted seven days' leave of absence en route to rejoin station.

Smith, F. C., P. A. surgeon, to assume temporary charge of Fort Stanton, N. Mex.

Duffy, B. J., asst.-surg., granted seven days' leave of absence from Aug. 12, 1911.

Clarke, F. M., A. A. surgeon, granted ten days' leave of absence, with pay, from Aug. 5, 1911, and fifteen days' leave of absence, without pay, from Aug. 15, 1911.

Earl, F. D., A. A. surgeon, granted two days' leave of absence, July 30-31, 1911.

Richter, H. C., A. A. surgeon, granted thirty days' leave of absence from Aug. 1, 1911.

Savage, W. L., A. A. surgeon, granted thirty days' leave of absence from Aug. 8, 1911.

Simonson, G. T., A. A. surgeon, granted two days' leave of absence, Aug. 4-5, 1911.

Storrs, H. R., A. A. surgeon, granted seven days' leave of absence, without pay, from Aug. 3, 1911.

Walker, H. D., A. A. surgeon, granted twenty-five days' leave of absence, without pay, from Aug. 7, 1911.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

IOWA: Capitol Building, Des Moines, September 19-21. Sec., Dr. Guilford H. Sumner.

MASSACHUSETTS: State House, Boston, September 12-14. Sec., Dr. Edwin B. Harvey.

MISSOURI: Kansas City, September 25-27. Sec., Dr. Frank B. Hiller, Jefferson City.

NEW YORK: September 26-29. Mr. Harlan H. Horner, Chief of Examinations Division, Department of Education, Albany.

Wisconsin May Report

Dr. John M. Beffel, secretary of the Wisconsin Board of Medical Examiners, reports the written and oral examination held at Milwaukee, May 24-26, 1911. The number of subjects examined in was 22; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 69, of whom 68 passed and 1 was conditioned. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Northwestern University Medical School	(1872)	84.
Rush Medical College	(1911)	87.
Bennett Medical College	(1911)	81.

Connecticut Homeopathic July Report

Dr. Edwin C. M. Hall, secretary of the Connecticut Homeopathic Medical Examining Board, reports that at the meeting held July 11, 1911, 1 candidate, a graduate of the New York Homeopathic Medical College and Hospital, 1899, was licensed through reciprocity with New Jersey.

Book Notices

Ueber Scharlach (der Scharlacherkrankung zweiter Teil). Von Dr. Dionys Pospischill, k. k. Primararzt, und Dr. Fritz Weiss, gew. Assistent der Abteilung. Paper. Price, 5 marks. Pp. 147. Berlin: S. Karger, Karlstrasse 15, 1911.

The authors have had enormous experience with scarlet fever. This work is based on the study of 3,605 cases seen within the six years ending with 1909 and especially on 2,605 cases seen during the last thirty-five months of that time. During these and previous years the authors have gathered a number of deep-rooted impressions and convictions about scarlet fever, and they express these with an earnestness and a fervor that is rather unusual in a scientific treatise. Only a single page is devoted to statistics. The authors aim rather to record their views which are the results of years of careful clinical observation. Pathology, bacteriology, hematology, etc., remain almost untouched—the work is essentially a clinical treatise.

This pamphlet is devoted wholly to what the authors call *das zweite Kranksein*, i. e., the second manifestation of illness in scarlet fever that occurs after the primary symptoms have abated or disappeared. This *zweite Kranksein* is not a complication, or a new illness; it is an integral part of the scarlet fever process. The symptoms when present are, in order of frequency, one or more of the following: (1) fever; (2) adenitis; (3) angina; (4) nephritis; (5) scarlet fever heart.

Special attention is given to nephritis and to the severe types of scarlet fever. Before the latter, the authors feel utterly helpless in affecting its course. In two series of 1,186 cases, each of the children kept on a milk diet on the one hand and on a general diet including rest; on the other hand, there was a difference of 1/6 of 1 per cent. in the number of cases of nephritis that developed. Mastoiditis, the authors state emphatically, should never be operated on radically. Moser's serum they consider of value.

The book is interesting alike to the student and practitioner of limited experience with scarlet fever, and to the specialist who has seen a great deal.

Medical Revolution. A Plea for National Preservation of Health Based on the Natural Interpretation of Disease: By Sydney W. Macilwaine, M.R.C.S., L.R.C.P. (Retired). Cloth. Price, 2 shillings 6 pence. Pp. 162. London: P. S. King & Son, Orchard House, Westminster, 1911.

This little book is a plea for a national preservation of health based on the natural interpretation of disease and is dedicated to the "intelligent and puzzled layman, to medical officers of health and general practitioners and to medical students to whom belong the future of our profession." The emphasis laid by the writer on prevention rather than cure is another indication of the rapidly changing views regarding the function of the medical profession. Probably the most suggestive and practical chapter is that on organization, in which Macilwaine pleads for a systematic and intelligent effort to make the collective experience of the entire medical profession of value to each member. After discussing the enormous practical experience of individual physicians at the end of long years of service, and of the profession in the aggregate, he says, "We have no organization for the collection, digesting and systematizing of experiences. The vast bulk of our raw material is deliberately allowed to die unorganized and unrecorded with the individual practitioner." His remedy is simple. "There must be created a central body of experienced men who shall collect information from the whole profession bearing on the causation of disease. This information they will systematize and redistribute regularly to every member of the profession. As soon as our knowledge of any particular disease was definite enough for the purpose it would be drafted into a permanent shape and also distributed to the profession. In this way the foundation of the ultimate text-book of medicine would be made. It would represent the accumulated and systematized experience of the whole profession. It would be comprehensive and would furnish the practitioner at last with a complete and reliable book of health." It is interesting to note in this connection that much the same plan of collecting data from each member of the profession was proposed in the American Medical Association over fifty years ago but has never been developed into a practical working scheme. The book is of interest as an evidence of the changing attitude of the medical profession in England. Evidently our English brethren are going to lead the way in the inevitable socialization of the medical profession.

Clinical [illegible] l Reference to Life-Threatening [illegible] By Alois Pick, Professor of M[illegible] and Adolph Hecht, Pediatrician, St. Anne's Hospital, Vienna. An Authorized Translation Under the Editorial Supervision of Karl Konrad Koessler, M.D. (Univ. of Vienna), Instructor of Clinical Medicine, Rush Medical College, in Affiliation with the University of Chicago. Cloth. Price, $6 net. Pp. 833. New York: D. Appleton & Co., 1911.

The systematic grouping of the several diseases and pathologic conditions which may produce a given symptom, forms a valuable method for teaching differential diagnosis. Such a study enables the student to construct a mental cross-index to his store of facts concerning disease, and trains him in orderly habits of thought.

In this work Pick and Hecht discuss symptoms, such as vomiting, headache, pain in the chest, jaundice, etc., and after describing the mechanism by which the symptoms are produced, suggest appropriate therapeutic measures. This proposal of the authors to combine treatment with diagnosis is commendable. The diseases for which we possess specific remedies are relatively few in number, and treatment must often consist in alleviating the more distressing complaints of the patient. The study of symptoms offers a favorable opportunity for the discussion of rational therapy based on the pathologic condition present.

The opening chapter deals with general symptoms including nutritional and developmental anomalies, with a full discussion of the theories of the production of fever. The section on disturbance of heart action contains many valuable suggestions on treatment. We commend specially the chapters on dyspnea and pain in the chest. The space devoted to abdominal pain is rather limited, considering the importance of the subject. The subject of jaundice, too, deserves a more thorough consideration than is accorded to it by the authors. The chapter on the symptomatology of poisoning by chemical agents will prove of interest.

The translator has adhered closely to the subject-matter of the German edition. The inverted sentence is employed rather more frequently than is consistent with idiomatic English. Typographic errors are rare.

The book contains much that is valuable to the student, and to the clinical instructor who wishes to present his subject from a new point of view.

INTERNAL SECRETIONS FROM A PHYSIOLOGIC AND THERAPEUTIC STANDPOINT. By Isaac Ott, A.M., M.D., Professor of Physiology in the Medico-Chirurgical College of Philadelphia. Cloth Price, $1. Pp. 133, with illustrations. Easton Pa.: E. D. Vogel, 1910.

In these lectures Dr. Ott has undertaken to present a succinct account of the recent facts accruing from the study of the physiologic and pathologic action of the glands with internal secretion. The first and second lectures deal with individual glands, the parathyroids and the pituitary, the third with the correlation of such glands in the economy. Perhaps no better example of the nice adjustments of the animal economy can be produced than the action of the adrenals in producing a definite chemical substance, one-millionth of a grain of which raises blood-pressure and an excess of which might have very deleterious effects. The quantity and action of this secretion is so carefully regulated, however, that no harmful results arise in the normal animal. The study of the parathyroids brings out the records of a good deal of personal work on the part of the author. He found that tetany was due to a poison in the blood, but not entirely to loss of calcium. He found that the pituitary gland is able to some extent to compensate for failure of parathyroid function. In the second lecture, a more detailed study of the pituitary is made and some therapeutic deductions drawn. The author attributes acromegaly to hyperhypophysy and infantilism to hypohypophysy. He found that in experimental work none of the artificial preparations have as much power as the gland itself. The third lecture compares the action of the various glands and lays the foundation for the therapeutic deduction that overaction of one gland is to be controlled by giving the substance or secretion of another gland to counteract the effect of the first. A considerable number of therapeutic conclusions are here collected which naturally add to the interest of the work to the practicing physician. The book is quite profusely illustrated by a number of charts and tracings. Only a careful reading will disclose the full value of the facts which recent studies of the ductless glands have brought to light. Such a perusal we bespeak for this monograph.

LEHRBUCH DER [illegible] beitet von Prof. Dr. Feer, Heidelberg; [illegible] erlin; Priv.-Doz. Dr. Ibrahim, München; [illegible] Prof. Dr. Moro, München; Prof. Dr. Vc [illegible] Dr. Pfaundler, München; Prof. Dr. Thiemich, Magdeburg: Priv.-Doz. Dr. Tobler, Hei- [illegible] Prof. Dr. E. Feer, Direktor der Univ.- [illegible] Paper. Price, 11.50 marks. Pp. 734, [illegible] Gustav Fischer, 1911.

This is a composite book, but the names of the contributors are an evidence that the editor selected men of authority to discuss the various subjects. Thus, Finkelstein and Meyer write on nutritional disorders and diseases of the new-born; Pfaundler, on blood, constitutional and metabolic disturbances; von Pirquet, on tuberculosis and diseases of the respiratory tract; Moro, on syphilis and dermatology; Feer, on heart diseases and acute infectious diseases; Ibrahim and Tobler, respectively, on diseases of the nervous and genito-urinary systems, while Thiemich contributes a valuable introductory chapter of 100 pages on general considerations, anatomy, physiology, nutrition and hygiene, examination, symptomatology, pathogenesis, prophylaxis and therapy. The continuity and unity of the book are not disturbed because each author discusses a complete subject.

The illustrations are abundant, original, well chosen and well executed. The book is exhaustive in spite of its size, partly because of its conciseness and partly because of the fact that it treats briefly the diseases which are common to child and adult and fully those which are peculiar to the child. For this reason infancy receives the largest share of attention.

THREE THOUSAND YEARS OF MENTAL HEALING. By George Barton Cutten, Ph.D. (Yale), President of Acadia University. Cloth. Price, $1.50 net. Pp. 318, with illustrations. New York: Charles Scribner's Sons, 1911.

This is a general historical review of mental healing. As the author intimates in the preface, many people nowadays are misled into believing that the recent mental healing movements are new in origin and in principle, simply and solely because they are ignorant of similar movements in the past. The author's object in writing this book was to show, on the contrary, that such movements as those known as Mormonism, Dowieism and Eddyism—mental healing combined with religious vagaries—are merely repetitions of similar movements in bygone ages, and that such individuals as the "Mountain Evangelist," George O. Barnes, Father Mathew and Francis Schlatter (the latter only the other day was attracting thousands of intelligent people to Denver who stood in line for hours to receive his magic touch and be healed) present characteristics which are to all intents and purposes the same as those of "healers" and leaders of cults hundreds and thousands of years ago.

The author is not a physician; he is president of Acadia University (Nova Scotia) and writes from the point of view of an intelligent layman. He discusses briefly, but philosophically, the different individuals, movements and fads of the past—relics, talismans, amulets, charms, royal touch, mesmerisms, etc., leading up to the final chapter, "The Healers of the Nineteenth Century." He recognizes that there has been, and is, an element of truth underlying all these things—the influence of the mind on the body.

When one has read this book one will be forced to acknowledge that with all our boasted civilization, with all our education and intelligence, the average human being of to-day is just as susceptible to imposition, just as easily led astray, and just as superstitious, as was the average human being one, two or three thousand years ago; also that ordinary common sense and logical reasoning are as foreign to the modern individual who is carried away with some fad or fancy that is cloaked in mystery or befogged with the supernatural, as they were to the individual human being one thousand years before Christ.

EDUCATION: HOW OLD THE NEW. By James J. Walsh, M.D., Dean and Professor of the History of Medicine and of Nervous Diseases at Fordham University School of Medicine. Cloth. Price, $2 net. Pp. 459. New York: Fordham University Press, 1910.

This volume contains eleven lectures and addresses. Of particular interest are the chapters on "The First Modern University"—that of Alexandria—"Ideal Popular Education," and "The Medical Profession for Six Thousand Years." Dr. Walsh shows in his interesting style that high ideals in education are not solely the product of recent decades, but were held and to a great extent fulfilled in ancient times. He shows also that much information of value may be obtained from a study of the history of education. In fact, he shows that the standards of medical education of a few decades ago were far inferior not only to those held centuries ago, but also to those long held by the Spanish-American universities of Mexico and South America. This book is well worth reading, and will be a valuable addition to the library of any one who desires a broad outlook on the subject of modern education.

REFRACTION AND MOTILITY OF THE EYE. With Chapters on Color-Blindness and the Field of Vision. Designed for Students and Practitioners. By Ellice M. Alger, M.D., Adjunct Professor of Ophthalmology at the New York Postgraduate Medical School. Cloth. Price, $1.50 net. Pp. 376, with 122 illustrations. Philadelphia: F. A. Davis Co., 1910.

This useful compend, now a year old, has found favor with students of refractive errors and of oculomuscular anomalies. Beginning with a chapter on optics the author furnishes a good account of the fundamental principles of the reflection and refraction of light, especially in their relation to the physiology of the eye. This is followed by a description of the normal or emmetropic eye, of the ophthalmoscope and its uses, and by a fairly well-considered report on that important subject, retinoscopy, which, by the way, we would prefer to call "skiascopy." Then follow chapters on hyperopia, myopia, astigmatism, presbyopia, anisometropia, aphakia and binocular vision. Four good-sized sections of this text-book are devoted to the normal motility of the eye-ball and to the causes, diagnosis and treatment of its abnormal variations—heterophoria and heterotropia.

The subjects strabismus, squint and ocular paralysis (the writer apparently makes no distinction between "paresis" and "paralysis"), their causes, detection and cure, are also described in a manner very helpful to the student.

Just why, in a small work of this sort, chapters on color-blindness, the visual field and the relations of functional eye symptoms to general diseases are appended is not quite clear, unless it is held that every ocular interest may be regarded as more or less germane to the subject of refraction and heterophoria. The book is well made, fairly illustrated and has a capital index.

THE NERVOUS LIFE. By G. E. Partridge, Ph.D., Formerly Lecturer in Clark University. Cloth. Price, $1 net. Pp. 216. New York: Sturgis & Walton Co., 1911.

The author endeavors to point out some of the causes and conditions of the nervous, social and industrial life of our people as a whole, as well as the nervous life expressed in the temperament of the nervous individual. He holds that as the causes responsible for present conditions are rooted in the very heart of our national life and, indeed, of all social progress, the cure must be as profound and broad as the disease and must include the whole problem of education, mental and nervous hygiene and the personal problem of each individual. He endeavors to point out especially the psychologic causes and conditions of the nervous life and to suggest methods by which such conditions should be controlled. Chapters on biologic laws and self-knowledge serve as introductory. In Chapters 6 and 7, on the principles of control and the optimum life, the author defines his theory. The remainder of the book is devoted largely to discussing the practical means by which better conditions can be brought about. Food, exercise, rest and sleep, work and recreation are all discussed. The subject is one of vast importance and the book should be welcome as a contribution to a better knowledge of the complex conditions of modern life.

A TEXT-BOOK OF MEDICINE. For Students and Practitioners. By Dr. Adolf v. Strümpell, Professor of Special Pathology and Therapeutics at the University of Leipsic. Fourth American Edition. Translated by Permission from the Seventeenth Revised German Edition with Editorial Notes, Additional Chapters, and a Section on Mental Diseases, by Herman F. Vickery, A.B., M.D., Instructor in Clinical Medicine, Harvard University, and Philip Coombs Knapp, A.M., M.D., ex-President of the American Neurological Association. Cloth. In Two Volumes. Price, $12 net. Pp. 831 and 800, with 224 illustrations. New York: D. Appleton & Co., 1911.

It is twenty-five years since the first American edition of Professor Strümpell's text-book was published and ten years since the third American edition, translated from the fourteenth German edition, appeared. The present is the fourth American edition, corresponding to the seventeenth German edition. These facts are an evidence of the well-deserved popularity of this text-book, both in America and in Europe. The present edition has been brought well up to date by the addition of articles on the "fourth disease," Malta fever, Rocky Mountain fever and pellagra. The editors have also included a section on mental diseases, which are of interest to the general practitioner. The present edition, we are sure, will be accorded the same favorable reception as its predecessors.

A MANUAL OF THE DISEASES OF INFANTS AND CHILDREN. By John Ruhräh, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Third Edition. Flexible leather. Price, $2.50 net. Pp. 534, with 173 illustrations. Philadelphia: W. B. Saunders Co., 1911.

Three editions in three years speaks well for a work of the size and scope of this. It is deservedly popular, inasmuch as it gives the busy practitioner a concise account of practically everything in this field. For a more detailed and discursive text larger works must be consulted. It is not intended to be more than a desk-book. Besides having revised the entire text, the author has added a dose-table of drugs, instructions for summer, the care of the mentally deficient, the blind and the deaf. The book is well illustrated by pictures and plates as well as charts.

Medicolegal

Right to Recover for Operation Followed by Death—Power of Wife to Bind Husband for Operation on Child

(French vs. Burlingame (Mo.), 134 S. W. R. 1100)

The St. Louis Court of Appeals here affirms a judgment for the plaintiff for the reasonable value of professional services rendered as a surgeon in performing an operation on the defendant's infant daughter, for which a charge of $100 was made. The defendant, father, resisted payment solely on the ground that the operation was performed without his knowledge or consent. The child, 9 years of age, was suffering with what was diagnosed as an abscess of the liver. The mother had brought the child to the city and was advised that an operation should be performed at once in order to permit the pus to escape, and thus save the patient's life. She agreed that the operation should be performed, and it was, at a hospital, on the following day, when it was said that as much as 2 quarts of pus were removed. It was conceded that the operation was performed with skill, and that the death of the child, which occurred a day or two afterwards, was caused by weakness resulting from the disease. It was in evidence on the part of the defendant that he had objected to an operation before his wife left home with the child, and said that one should not be performed, but that fact was not communicated to the plaintiff, who was informed only that the father objected to the child's being removed to St. Louis.

The defendant relied on the case of Detwiler vs. Bowers, 9 Pa. Super. Ct. 473, where it was said that a surgical operation of doubtful advantage was not a necessary for which a non-assenting father was liable on an order given to the surgeon by the wife. But the facts in that case were dissimilar from those in this one, for there the malady from which the child suffered and for which the operation was performed at the instance of the mother, without the knowledge and against the consent of the father, was a cancerous tumor, and the parents had been advised that the disease would immediately reveal itself again, though an operation were had. Indeed, this prediction proved to be true in that case, for, though several operations were had, each time the cancerous growth recurred. On those facts, the court deemed the operation so known to be of doubtful advantage as one not falling within the category of necessaries furnished the child for which the parent should answer.

Here the facts were entirely dissimilar, for naught in the case suggested that the malady—an abscess of the liver—might return if once removed, and it was conceded that its removal was the only remaining chance for the recovery of the child. The fact that the defendant objected to the child being removed from home and brought to St. Louis for treatment by the plaintiff was wholly unimportant in view of the further fact that, notwithstanding, he permitted the removal to be made.

The defendant having acquiesced in the act of his wife in bringing the little one to the plaintiff in St. Louis for treatment, the case must be viewed as though the wife was his agent for the purpose. No one can doubt the implied agency of the wife to pledge her husband's credit for necessaries for herself or his minor children according to the circumstances of the case. It is the law, too, that the father is liable for such reasonable necessaries of life as are compatible with his circumstances furnished to his minor child by third persons in case he neglects to supply them, and they are procured by the child, or even by a prior divorced wife, for it.

It was conceded that the only chance of saving the life of the child was the operation, which the plaintiff performed in a careful and skillful manner. The fact that the patient subsequently died without fault of the surgeon was wholly immaterial to the obligation of the defendant to pay the reasonable value of his services.

In these circumstances, the court can imagine nothing more highly necessary to the welfare of the child or more within the obligation of the parent than the services rendered, for it was the one and only hope of the little one's continued life to bless and cheer the parents. It was obvious, too, that this service was rendered at the instance and request of the defendant's wife, who possessed *prima facie* authority to bind him for such necessaries as were furnished to herself or his minor children. Infection was present and about to progress. The mother, unattended, except by the family physician, but with the father's consent, was in a great city with their child dangerously ill, seeking some measure of relief. So situated, was the mother to await communication with her husband at a distant part of the state, while the spell of almost immediate dissolution hovered over the little one, before asserting her authority to commit him to respond as for necessaries in compensation of services which offered the one chance for its life? The court answers no. It further says that the services rendered were in the circumstances of the case necessaries for which the law implied an obligation on the part of the father to pay when so performed at the instance and request of the mother. Every precept of natural justice suggests the liability of the defendant, and, if there is no precedent for sustaining the judgment, one should be established forthwith.

Incompetent Evidence to Fix Liability on Company for Services

(Chickasha Cotton Oil Co. vs. Lamb & Tyner (Okla.), 114 Pac. 333)

The Supreme Court of Oklahoma reverses, for errors in the admission of evidence, a judgment recovered in this case against the oil company, by the latter-named parties, for services rendered as physicians to a wounded employee. The plaintiffs sought to fix liability on the company for their services by showing that the company's manager sent for them and requested that they render the services. Over the company's objection, they were permitted to testify that the person who called for them at the time of the accident stated that he had been sent by the president or manager of the company. But there was an entire absence of any other evidence in the record to show that the person who made this statement was in any way the agent of the company, or had been sent by its manager, and it is held that statements made in the absence of the defendant by the messenger, who was not shown to be the company's agent, could not bind the company, and were objectionable as hearsay testimony.

The company's defense was that its manager had not ordered the services of the plaintiffs; and that, if he had done so, he was without authority to bind the company in the premises. The company offered to prove by the manager that he was without such authority; but his testimony relative thereto was rejected by the trial court. That such testimony was competent seems plain; it bore directly on the issues of defense made by the company's answer. The burden was on the plaintiffs, under the issues formed by the pleadings, not only to show that the company's manager requested them to render the services for which they sought to recover, but also that he was acting within his authority as the agent of the company; and evidence by the company's officer who knew his authority was competent to contradict evidence offered by the plaintiffs in support of this issue.

It was also error to permit the plaintiffs to testify in their own behalf as to a conversation had between them and one Morrison, in which he made statements tending to show the admission by the company of its liability to the plaintiffs for their claim. They testified that he had asked them if they were still looking to the company, and, on being told that they were, said to them that they had better see the company about standing for any more of the bill; that the company had some money on hand that it expected to pay on the plaintiff's bill, but, before the plaintiffs did anything else, they had better see the company, as their bill was much more than the company was expecting anyhow. Morrison was an employee of the company, but to render the admissions of an agent admissible against his principal it must first be shown by competent evidence that such admissions were made in and as a part of the agent's performance of his duties and within the scope of his authority, which the record did not show in this case.

Physical Examinations of Policemen and Plaintiffs

(People ex rel. Wayman vs. Steward (Ill.), 94 N. E. R. 511)

The Supreme Court of Illinois holds that a rule making it the duty of the superintendent of police of the city of Chicago to ascertain, by physical and medical examinations conducted under his direction from time to time by a board of physicians, whether active patrolmen are able to perform the duties required of them, to the end that he may make assignments of patrolmen to such duties as they shall be physically able to perform, and that if any are permanently or totally incapacitated he may prefer charges of physical incapacity against them before the Civil Service Commission, does not violate the constitutional provision: "The right of the people to be secure in their persons, houses, papers and effects, against reasonable searches and seizures, shall not be violated." Courts have never looked on a physical examination to determine the fitness of a person for a particular service as a search, within the meaning of the constitutional provision. The case of a policeman is like that of a soldier, where physical ability is necessary and material part of an examination. It is not contended that the superintendent has authority forcibly to make, or cause to be made, a physical examination of a member of the police department. If a policeman does not choose to submit to the examination and to abide by the rules and regulations of the department, he merely commits the offense of disobeying the superintendent, and subjects himself to a charge of that kind before the Civil Service Commission.

An argument was drawn from the rule of this court that in a civil suit the court has no power to compel a physical examination of a party to the suit, but there is no similarity between the two cases, nor is there any claim that the superintendent may compel the examination of a policeman. Besides the rule that the court cannot compel an examination of a party does not rest on immunity, under the Constitution, from an unreasonable search. There is no doubt that a statute might be enacted requiring a party to submit to an examination as a condition of maintaining the suit, and many courts have held that such an examination either rests in the discretion of the court, or may be demanded by the opposite party as a matter of right.

In any view of the case, the court cannot see how it can be said that the superintendent of police is compelled by the Constitution to remain in ignorance of the physical capacity of policemen to perform the duties required of them, with the necessary consequence that the policemen may retain positions which they are incapacitated to fill and draw salaries for services they are unable to perform. Even if the examinations conducted for the purpose of ascertaining the facts should be characterized as searches of the person, they cannot be considered unreasonable.

Form of Action and Liability for Malpractice—Expert Testimony

(Carpenter vs. Walker (Ala.), 54 So. R. 60)

The Supreme Court of Alabama affirms here a judgment for damages for alleged malpractice in the setting and treating of a compound fracture of the forearm for a boy whereby it was charged that he lost his arm. It says that the action against a physician for malpractice need not be based on a contract, though it may be, and usually is. It is sufficient if based on his legal obligation. The action for malpractice is essentially in tort (for wrongdoing), and hence it is immaterial by whom the physician is employed. While a physician or surgeon may, under the same state of facts, be liable both *ex contractu* and *ex delicto*, or on contract and for breach of duty, yet the plaintiff has the option to declare against him in either form; but prior to the present Alabama Code he could not declare in both in the same action. As to the duty, care and skill required of physicians and surgeons, the rule (as twice before announced) is as follows: "the reasonable and ordinary care, skill and diligence which the law requires of physicians and surgeons in the same general neighborhood, in the same general line of practice, ordinarily have and exercise in a like case."

There was no error in allowing the question to be propounded to a medical witness, "whether it was reasonable prudence on the part of a surgeon setting a broken limb to leave the patient for ten days without any one trained in treating wounds, and with instructions to his parents that he need not be sent for unless the hand turned black." There was evidence justifying the hypothesis put; and it was not a substitution of the witness for the jury, but was to afford them the benefit of an expert's opinion as to whether that kind of treatment was reasonable prudence.

Nor was there error in instructing the jury that if they believed from the evidence that the plaintiff broke his arm, and that the defendant was employed by the plaintiff's father (plaintiff being a minor) to treat and attend the same as a physician and surgeon, and entered on and undertook such employment, and did set or dress or treat the plaintiff's said arm as a physician or surgeon, and assumed charge of the same, then the plaintiff was entitled to receive from the defendant the care, attention and skill of an ordinarily skilled physician and surgeon. And if the jury believed that the plaintiff did not receive from the defendant such care, attention and skill, and that in consequence of not receiving the same, and without fault on the plaintiff's part, or on the part of any one else, suffered increased pain, suffering and injury, then the jury were instructed that the defendant was liable, and the jury would render a verdict for the plaintiff, and would assess his damages found from all the evidence, not exceeding the amount claimed by the plaintiff in his complaint.

AMERICAN OPHTHALMOLOGICAL SOCIETY

Forty-Seventh Annual Meeting, held at New London, Conn., July 11-12, 1911

(Concluded from page 680)

Sarcoma of the Chorioid; Neuromata of the Ciliary Nerves

Prof. E. Fuchs, Vienna: I believe these to be the smallest specimens of sarcoma of the chorioid hitherto known. There were three cases in all. In one, the sarcoma was so minute that it could not be seen by means of the ophthalmoscope.

The only positive evidence that these small tumors are sarcomas would be an aggressive and destructive growth, which could not be expected at such an early stage. The diagnosis must, therefore, be based on the character of the cells composing them.

In the first and third cases, the tumor was composed of closely packed spindle cells, with scarcely any pigment. In the second case, the pigment cells composing the tumor assumed in part a polygonal shape, and lay contiguous to one another, like spindle cells. We may learn from these cases that the sarcoma may originate in the layer of large vessels termed Keller's layer; it may be composed of spindle cells from the beginning, and deep pigmentation may be present from the very start. I have found neuromata in two atrophic eye-balls.

In both cases, the minute tumors were composed nearly exclusively of nerve-fibers; so that they were genuine neuromas, and not neurofibromas.

DISCUSSION

Dr. George E. de Schweinitz, Philadelphia: A few years ago, Dr. E. A. Shumway, of Philadelphia, and I showed two growths of the chorioid. Dr. Fuchs, in a recent paper on sarcoma, referred to these, and stated that we had left it open whether they were to be regarded as sarcomas or degenerated chromatophores. He has just pointed out that young sarcomas never form chromatophores. One of our cases was a melanoma, and the other a sarcoma of the chorioid.

Cases of Pulsating Exophthalmos Cured by Ligation of the Common and Internal Carotids

Dr. William H. Wilder, Chicago: Both cases were due to blows on the head. Exophthalmos was marked, but pulsation was very slight. In one case relief immediately followed ligation of the common carotid, and a permanent cure resulted. In the other case ligation of the common carotid gave relief from the bruit and the head noises, but the exophthalmos did not recede completely. A recurrence of the bruit and an increase in the exophthalmos took place two months after the ligation. The internal carotid of the same side was then ligated, with complete relief of all the symptoms, and the results have been permanent up to date. A slight impairment of speech and paresis of the left forearm followed ligation of the internal carotid.

DISCUSSION

Dr. Samuel D. Risley, Philadelphia: I should like to inquire whether, after the ligation of these arteries, if there were intra-ocular hemorrhages in either of the cases. Some time ago, I reported one instance in which, when I made an ophthalmoscopic examination, forty-eight hours afterward, I found extensive hemorrhages that had been absent before the operation.

Dr. Carl Fisher, Rochester, Minn.: Dr. Charles Mayo operated about a year ago in a similar case. This patient had had a pulsating exophthalmos of the left eye, for which a ligation of the common carotid had been done some time before. Through some accident, this eye had afterward been lost. Three years later, the patient developed pulsating exophthalmos of the right eye. The vision remained fair, but was slowly diminishing. Dr. Mayo clamped a stout tin spring around the vein. He then closed the artery as much as he could allowing vision to remain, so as to develop collateral circulation through the basilar arteries. It is hoped that enough collateral circulation may be developed to enable the woman to retain her vision.

Dr. Emil Gruening, New York City: I have had two cases of pulsating exophthalmos; both patients were operated on by ligation of the common carotid. There was almost immediate improvement of the sight, and no hemorrhage occurred.

Dr. William H. Wilder: There were no retinal hemorrhages in either of my cases. I should hesitate to ligate the ophthalmic vein until I had resorted to other procedures, as I should fear embolism somewhere in the body, particularly the brain.

Phantom Intra-Ocular Tumor

Dr. Arnold Knapp, New York City: The patient was a woman, aged 73, with protrusion of the left eye. Palpation at the margin of the orbit was negative, except at the upper inner angle, where a nodular pulsating mass was felt. The optic nerve was normal. The fundus showed arteriosclerosis of the vessels, with a few small hemorrhages; and below, in its periphery, there was a shallow detachment. The pupil was dilated, and there was a round, brownish swelling back of this on the temporal side. Tension was normal. The diagnosis of intra-ocular tumor with orbital extension seemed clear. The growth was thought to be a melanosarcoma of the ciliary body. Enucleation showed cystic degeneration of the retina, with distinct changes in the epithelium in the pars ciliaris retinæ. The tumor recognized clinically was presumably a large cyst or detachment, which ruptured when the eye was opened immediately after removal.

The Field of Vision in Tabetic Atrophy of the Optic Nerve

Prof. E. Fuchs, Vienna: Ybllhoff states that the cases of tabetic atrophy in which the field of vision presents a central scotoma constitute about 2 per cent. of all the cases of tabetic atrophy. According to my experience, they are more common; as I could pick out not less than thirty from the histories of my private patients alone. The common opinion is that the central scotoma is not a sequela of the tabes, but is to be considered as a complication with a simultaneous syphilitic retrobular neuritis. I believe, however, that we have to do with the same kind of gray degeneration that is characteristic of tabetic atrophy in general. As a rule, the spots of gray degeneration are located in the optic nerves, but they may exceptionally locate themselves farther back in the chiasma. According to my belief, bitemporal hemianopia is in most cases of tabes to be considered, not as an accidental complication due to hypostatic inflammation, but as a genuine tabetic affection.

DISCUSSION

DR. GEORGE DE SCHWEINITZ, Philadelphia: I should like Dr. Fuchs to tell us whether the results of his observation indicate that the excessive use of tobacco and alcohol has any bearing on the existence of the central scotoma. I had always supposed that instances of central scotoma were much rarer than 2 per cent.

DR. LUCIEN HOWE, Buffalo, N. Y.: I have found that if the center of the eye did not correspond with the center of the arc of the perimeter, it was not difficult to get almost any kind of field that was desired.

DR. E. FUCHS: It was not 30 per cent. of cases of tabetic atrophy that showed a central scotoma, but thirty cases out of many hundreds. All the patients were men, as is usual in tabes; and there was none of them who did not smoke. The man from whom the specimen came was a heavy smoker. If it had been a toxic scotoma, the stopping of the use of these drugs would have brought about an improvement in the scotoma. I used MacHardy's self-regulating perimeter, the ordinary perimeter, and the campimeter. If you examine the patient on subsequent days, you will not find the results exactly alike, because the fixation is not sure.

The Mechanics of Choked Disk

DR. MYLES STANDISH, Boston: Following an operation on the mastoid, there was thrombosis of the lateral sinus; although it still remained permeable. The patient was operated on, ligature of the jugular vein being done. There was an increase of choked disk on the side operated on, followed by similar appearances in the other eye. These symptoms finally subsided, and the patient recovered.

Cilioretinal Vessels

DR. EDWARD JACKSON, Denver: Such vessels have been observed in 1,000 eyes, with notes of their position in each case. They are almost invariably arterial branches, and can usually be traced from their point of entrance into the optic nerve head. In doubtful cases, arteries may be distinguished from veins by noting which branches of the central retinal vessels they cross. Visible arterial pulsation under normal conditions appears to be more frequent in cilioretinal branches than in branches of the central retinal artery. This may be due to their manner of entering the eye-ball.

DISCUSSION

DR. B. A. RANDALL, Philadelphia: It is certain that, while the veins are far less frequently seen in this condition than are the arteries, they constitute a larger proportion than is indicated by Dr. Jackson, while it is almost invariable that vein crosses vein, and artery crosses artery, this is not always so.

Case of Retinitis Pigmentosa Complicated by an Albuminuric Retinitis

DR. T. B. HOLLOWAY, Philadelphia: The patient was a male, aged 34, who dated the onset of his ocular trouble from an attack of measles that he had had at the age of 9. Nephritis had been known to exist for about four years. Each eye showed lenticular and vitreous opacities. The disks were partially atrophic; and, in addition, the left disk had a distinct blurring of the temporal margins. The retinal vessels were contracted. In each macular region there was a stellate figure, and in the mid zone and periphery was a marked pigmentation characteristic of a retinitis pigmentosa. The fields were contracted to about 15 degree.

A Case of Embolism of the Right Central Artery in a Boy Aged 8

DR. E. GRUENING, New York City: The boy was examined twenty-four hours after the occurrence of the blindness of the right eye, and it showed the ophthalmoscopic picture of embolism of the central retinal artery. In the white zone surrounding the cherry-red spot there were numerous hemorrhagic patches. At present, white patches of peculiar appearance occupy the site of the macula. Embolism of the central retinal artery in children seems to be very rare. The secondary changes in the fundus are unusual.

DR. ALEXANDER DUANE, New York City: I had a case of bilateral partial embolism in a boy of 14, the patient being affected with heart disease.

DR. WILLIAM K. ROGERS, Columbus, O.: A case of the kind once occurred in my own practice. The patient was a boy of 10, who presented a characteristic picture of embolism of the central artery, but is was accompanied with a history of endocarditis, associated with chorea.

Congenital Deviations of the Eyes

DR. ALEXANDER DUANE, New York City: The characteristic marks of a congenital deviation cannot always be relied on. The most frequent forms of congenital deviation are the following: insufficiency of the superior rectus with or without secondary deviation; insufficiency of the inferior rectus; insufficiency of the external and internal rectus, usually combined so as to constitute a special syndrome. In most cases, the anatomic conditions underlying the deviations probably consist of aphasia or other defects of the muscles themselves. Contrary to what is generally supposed, the symptoms of congenital deviation are often important and cause permanent inconvenience. They comprise obvious squint (which may be present at the outset or may not develop until late in childhood), torticollis, asthenopia and aprosexia. The treatment consists in operation. Each case must be judged by itself.

The Function of the Kidney Glomerules.—In his Croonian lecture before the Royal Society of Great Britain, Prof. T. G. Brodie brought out a new conception of the glomerular activity. Recent work, he says, has conclusively shown that the usual explanation of the glomerules, that they act as filters, is incorrect. Excluding filtration, the structural details point to a relation to the blood-pressure in the work of the glomerules, and he suggests as their function the setting up of a pressure head by which the watery part of the urine is driven through the very long and narrow tubules. Its activity would be, therefore, one of propulsion, and he suggests that the glomerulus be called a "propulsor." He finds, by an approximate calculation, that to drive the fluid through the tubules during the height of the kidney activity, a pressure head about equal to that in the glomerular capillaries is required. In support of this he offers the microscopic findings in the kidney after activity. The capsules of Bowman are greatly distended, the glomeruli are moderately enlarged and no longer fill the capsular spaces, and the tubules are straightened out and distended. All these changes are exaggerated by anything that favors the exaggeration of this intratubular pressure, such as a high arterial blood-pressure or obstruction to the outflow through the ureter. The kidney, moreover, is tense and hard, and its capsule stretched to the utmost. The presumption of the propulsor function of the glomerules he says explains the existence of a firm and inextensible capsule to the kidney, and also such phenomena as the maximum ureter pressure, the dependence of the rate of discharge from the kidney on the general blood-pressure and dilatation of the renal arteries, etc. Applying this theory, he says, to the study of the action of diuretics in animals in which the blood-pressure has been lowered so that the propulsion can no longer occur, we obtain evidence as to the parts of the renal tubules acted on by these different substances.

7 *Relation of the Adrenals to Pancreatic Activity. C. W. Edmunds, Ann Arbor.

1. **Influence of Oxygen on Circulation.**—In a man with pulmonary emphysema, chronic bronchitis, and recurring cyanosis not associated with dyspnea, the blood-flow in the hands was increased by oxygen inhalation by an amount varying from 30 to 70 per cent. of the combined flow in the two hands in experiments made on different days during a period of two months. In general, a greater percentage increase under oxygen inhalation was obtained by Stewart when the initial flow was relatively small than when it was large. In this patient the normal flow (without oxygen inhalation) was habitually large, quite as large as in any of the normal cases studied, and larger than the average of the normal cases. The action of oxygen on the blood-flow was not associated with any sensible change in the respiratory movements, nor with any certain change in the alveolar carbon dioxid tension. Stewart is of the opinion that it was therefore conditioned in some way by the increased alveolar oxygen tension. Oxygen inhalation produced no sensible change in the rate of the blood-flow in the hands of two normal men.

2. **Antimonial Compounds.**—Many experiments on trypansome infected rats were made by Rowntree and Abel to determine the therapeutic value of antimonial compounds. They found that although the antimony salt of succinic acid is capable of causing the disappearance of trypanosomes, yet in the vast majority of cases its action is of very short duration. It is irritant locally, more toxic than the sodium antimony thioglycollate or the triamide of antimony thioglycollic acid, and much less efficient in the treatment of experimental trypanosomiasis.

7. **Adrenals and Pancreatic Activity.**—The results obtained by Edmunds in his experiments would seem to dispose finally of any objection which could be raised against the explanation that the inhibition of the pancreas by epinephrin (adrenalin) is due to the vasoconstriction and consequent anemia of the gland. Briefly, the evidence in favor of such a view is as follows: After doses of ergotoxin which paralyze the vasomotor nerves, epinephrin no longer causes constriction of the vessels of the gland, nor does it inhibit it. Pituitary extract will not inhibit unless it constricts the vessels of the gland. Nicotin and strychnin in their primary stimulant doses constrict the vessels of the pancreas and inhibit its action. Later, after the paralytic stage has come on, neither drug lessens the blood-supply to the gland, nor does either cause inhibition. Other drugs, such as strophanthin, pilocarpin and barium chlorid, which constrict the vessels of the gland, cause inhibition. If, on the other hand, they increase the blood-flow to the gland, as shown by increasing its volume, they have a tendency to accelerate the flow. Direct electric stimulation of the splanchnic nerve will produce precisely the same inhibition as will chemical stimulation.

21 Chemical Condition of Lake Water After Chlorin Treatment. H. D. Haskins and S. A. Cleaveland, Cleveland.
22 Hypertension of the Portal System. M. Schott, Cleveland.
23 Routine Bacteriologic and Chemical Examinations of the Cleveland Milk-Supply. H. O. Way, Cleveland.

17. **Blood in Pertussis.**—McGay examined the blood in forty-six cases of pertussis. In all the cases a leukocytosis of from 7,600 to 46,000 was found, as well as a lymphocytosis, with a decrease in the polymorphonuclears. Comparing the averages in forty-six pertussis cases with ten normal cases, there is an average increase of 6,070 in the leukocyte count, or approximately 33 per cent.; an increase of 1.9 per cent. in the large mononuclears, and of 5 per cent. in the lymphocytes, and a decrease of 6 per cent. in the polymorphonuclears; the transitionals, eosinophils and mast cells remaining approximately the same. In bronchitis and pneumonia the polymorphonuclear count is much higher than in pertussis, while the lymphocyte count, both small and large, is considerably decreased. The lower the leukocyte count, the higher the lymphocytes and the lower the polymorphonuclears; and as the leukocytes increased so did the polymorphonuclears, while the lymphocytes decreased in relatively the same proportion. The cases showing the lowest leukocyte count at the beginning of the child's coughing were the ones soonest well of the disease, except in one case, which held out as long as any, while another case had a recurrence with a count very similar to the one listed. The only fatal cases in the 120 directly attributable to whooping-cough were the ones (five in number) showing the highest leukocytosis. Four of the five fatal cases were caused by pneumonia complicating the pertussis; the fifth death resulting from gastro-enteritis.

19. **Major Hysteria.**—The case reported by Drysdale was of interest on account of the unusual combination of somatic phenomena appearing in one patient, i. e., hysterical paraplegia, multiple contractures, hemianesthesia, hyperesthetic zones, amblyopia, dyschromatopsia, unilateral anosmia and ageusia, bradylalia, amnesia, contraction of the psychic functions, etc.

33. Bisulphate of Quinin in Acute and Subacute Gonorrheal Urethritis.—Mowry has used bisulphate of quinin irrigations in fourteen cases of acute gonorrheal urethritis, and he says his results have been gratifying in most of the cases. Fifty per cent. of the patients have apparently been cured in the course of two weeks. In using the solution of bisulphate of quinin for irrigation purposes, Mowry begins with a solution of 1 to 3,000, and gradually increases the strength to 1 to 1,500. He uses the solution as warm as the patient can comfortably bear, with care always taken to avoid mechanical irritation to the meatus by the irrigating tip, and that the flow is continuous by not putting on too much pressure and still putting on enough to insure the solution getting well into the urethra. He has also used the above-described solutions in two cases of cystitis 1 to 5,000 with good results, and in four cases of chronic posterior urethritis with a fair result. In the latter cases he used the solution 1 to 400 in form of an instillation, using the Ultzman deep urethral syringe. As an anterior injection for the patient's own use, Mowry makes the strength of the solution 1 in 200 to 1 in 1,000.

51 Garbage Receptacles. P. M. Hall, Minneapolis.

47. Antityphoid Vaccination in American Army.—In the United States Army the vaccination against typhoid was begun in March, 1909, and up to Aug. 1, 1910, 11,771 persons were vaccinated. The total number of doses administered was 31,556. It has been the practice to give three doses at ten-day intervals to as many volunteers as possible. Seventy-five per cent. have received the full course of three doses; 21 per cent. have received two doses, and only 4 per cent. have failed to receive more than one dose. The failure to receive the second dose has sometimes been due to refusal, but just as often to change of station, discharge, desertion, etc. The first dose is 500,000,000 bacteria, the second and third 1,000,000,000 each. Ninety-five per cent. of the men had little or no fever or discomfort, aside from the local reaction. This consists of a somewhat red and tender area at the point of inoculation, which is rarely troublesome, and usually disappears in from forty-eight to seventy-two hours. Among the vaccinated men, three cases of typhoid have occurred, while, during the same length of time, there were 306 cases among the unvaccinated. The three cases were all mild and ended in recovery. Russell believes that the first case was probably infected immediately before or after receiving the first dose, and was admitted to the hospital soon after the second; the diagnosis was confirmed by isolation of the bacilli from the stools. The other two cases were so mild that, in the absence of blood cultures, there remains some doubt as to the correctness of the diagnosis.

53 Myiasis Narium. I. W. Brewer, U. S. Army.
54 *Duration of Passive Immunity Against Tetanus. E. H. Ruediger, Manila.

54. Duration of Passive Immunity Against Tetanus.—According to the results obtained by others and by himself, Ruediger concludes that passive immunity against tetanus is of short duration. Where alien serum is used immunity disappears in about three weeks; with homologous serum the duration may be about two months. The longest period of passive immunity conferred by alien serum reported on seems to be six months, observed by Roemer and Sames. Passive immunity conferred to the guinea-pig by a moderate dose of tetanus antitoxin from the horse is of less than three weeks' duration. Passive immunity from a large dose (300 units) of alien serum appears to be only a few days' longer duration than that from a smaller dose (100 units).

66. Cancer.—This study by McGlinn is taken from the records of 8,515 post-mortem examinations made at the Philadelphia General Hospital from Sept. 12, 1867, to Sept. 1, 1909. In this series there were 457 cases of cancer. One patient out of every nineteen posted (18.6) had cancer. Cancer was found in males in 274 cases and in females in 179 cases; the sex not being specified in four cases. Eliminating the organs peculiar to the sex, the percentage for males was 72.5 and for females 27.5. The frequency as to age was as follows: Twenty to 39 years, forty-four cases; 40 to 49 years, ninety-three cases; 50 to 59 years, 107 cases; 60 to 69 years, 121 cases; 70 to 79 years, sixty-seven cases; 80 and over, 113 cases. The location of the cancer was: Stomach, 168 cases; uterus, forty cases; breast, thirty-eight cases; pancreas, thirty-six cases; esophagus, thirty-one cases; liver, twenty-six cases; rectum, eighteen cases; gall-bladder, eleven cases. Chronic tuberculosis of the lungs (healed foci) was found associated with cancer 197 times; acute pulmonary tuberculosis, seventeen times; tuberculous peritonitis, five times, a total of 219 cases. Gallstones were present in fifty-one cases. In the entire series of autopsies gall-stones were found in 507 of the cases. Kidney-stones in the cancer cases were found seven times. Other neoplasms noted in association with the cancer cases were as follows: fibroid of uterus, twenty-five cases; fibroid of ovary, one case; broad ligament cyst, one case; ovarian cyst, four cases; papilloma of ovary, two cases; sarcoma, one case; hypernephroma, one case. Syphilitic lesions were found in eight of the cases.

68. Acute Angulation and Flexure of Sigmoid a Causative Factor in Epilepsy.—Since his last report on this subject, Axtell has had two additional private cases and examined three asylum cases, making a total of ten private and twenty-six asylum cases. In the whole number of cases the same conditions in varying degrees were present excepting in one asylum case. A remarkable feature in connection with this case was that the abdominal examination excluded the possibility of the internal trouble being present. In this particular case the epilepsy was produced by a depressed fracture. This was the first case of a normal condition of the rectum and sigmoid found at the asylum. There was no angulation or impaction whatsoever; no gaseous distention of the cecum or history of persistent and obstinate constipation. Of the ten private patients only four persisted in the treatment for the rectosigmoidal difficulties. Of these four, three are practically relieved of the epilepsy, as well as the rectosigmoidal trouble. The fourth patient who persisted in the treatment for an acute angulation, thickening and ulceration at the rectosigmoidal juncture was made worse while taking treatment. The convulsions occurred three or four times per month. After the acute angulation, ulceration, hypertrophy and the prolapsed and impacted sigmoid were relieved, the convulsions ceased. He has had no recurrence for more than two months. The fact that the frequency of the convulsions was increased during active treatment is the most convincing evidence in Axtell's opinion that the cerebrospinal irritation was caused by the rectosigmoidal trouble.

73. **Intestinal Indigestion in Adults.**—The authors' studies have shown that these patients have the greatest difficulty in handling the cellulose in their diet. Therefore, they should be given a concentrated diet of high caloric value which will tax their weakened powers of digestion as little as possible and leave no bulky residue to irritate the hypersensitive colon. Such a diet must be controlled frequently by the stool examination, and the symptoms, such as flatulence, auto-intoxication, etc., and the relative amounts of starch, meats and fats adjusted to the individual. All vegetables and starches should be cooked very thoroughly, and those, such as beans and peas, which have resistant capsules should be passed through a sieve and puréed. Contrary to expectation, this diet rarely aggravates constipation and sometimes it even improves matters by relieving spasm due to bulky, irritant masses. It is well, however, to have the patient eat plenty of stewed fruit without skins or seeds. Stool examination seems to show that the diseased intestine is absolutely unable to deal with poorly chewed food, and many an indigestion can be cured by securing better conditions in the mouth. Nothing will help the severer enteroptotic cases more than fattening. In such cases the authors generally give a diet containing 3,000 to 5,000 calories and a large amount of fat, mainly in the form of cream and butter. There is generally some repulsion and disturbance for the first three or four days, but they have not as yet found a case in which the diet had to be given up, or in which it failed to produce the desired gain in weight. During the first few days the patient should be in bed, as the sagging intestines do their work very much better when they have fallen back into place. The practice many surgeons have of "fixing" one or two of the prolapsed organs is strongly condemned by the authors. They believe it is irrational and does not take into account the condition as a whole.

74. **Intestinal Indigestion.**—Smith defends the surgical treatment of this condition.

76. **Dermatitis Venenata.**—Within a few months Chipman has met with six cases of severe dermatitis of more or less extensive distribution, the reaction in each instance following the use of "Mrs. Potter's Walnut Tint Hair Stain." This preparation was found by the North Dakota Agricultural Experiment Station to depend "for its action on paraphenylene-diamin, a substance which when oxidized by means of a solution of hydrogen dioxid becomes an intense black."

77. **Perforated Duodenal Ulcer.**—The purpose of Allen in reporting this interesting case is to draw attention to the fact that simple drainage to the point of rupture is all that is necessary for a permanent cure; that breaking away adhesions to see and suture the perforation may add just enough shock to change a favorable to an unfavorable termination. The patient in this case recovered.

81. **Treatment of Abdominal Pain.**—Thomas believes that many chronic sour stomachs in belchers are due to colitis, and curable by appendicostomy with proper after-treatment. He condemns the uncalled-for use of the hypodermic syringe. He says it is more disastrous than the uterine curet.

84. **Curetting in Epithelioma.**—Out of 139 patients presenting epitheliomata, forty-four with fifty-three separate lesions were treated by Culver by curettage and the application of chromic acid crystals. The tumors were located as follows: nose, fifteen; cheeks, fourteen; ear shell, seven; forehead, seven; eyelids, five; and one each on upper lip, lower lip, neck, chin and back of hand. Twelve of the forty-four patients had previously been treated by one or more methods of treatment and there was either incomplete removal or recurrence from apparent complete removal. Five of the forty-four are now under treatment. Of the remaining thirty-nine, twenty-three of whom Culver had knowledge and who had twenty-seven different tumors have remained free from recurrence for periods of time varying from a few months to five years. Seven of the remaining sixteen never had recurrences or have not had up to the present time, and of six others information is unavailable. Three had recurrences and one of the five under treatment has a recurrence, making a total of known recurrences in four patients, practically 9 per cent. Subsequent treatment of the four has been along similar lines. Eleven patients have been treated with Roentgen rays following the removal of the crust formed by the cauterization with chromic acid. The points considered in the selection of cases are these: The lesion generally has been present many months, is either a firmly indurated plate or tubercle in the skin, of shiny, waxy appearance, pinkish or yellowish in color, showing distinct dilated capillaries near its surface, or it is an ulcerated lesion showing in some part of its periphery a raised, rolled or nodular firm, waxy border which presents the characteristic dilated capillaries, and having an irregular center with an uneven, easily bleeding base that discharges a viscid fluid which dries into dirty yellowish crusts. Its appearance is often greatly changed by added infection or by previous treatment, but some of the characteristics are always present. Metastatic processes are uncommon in this type of epithelioma, but are sometimes present, and if so an entirely different treatment is required, and if inoperable it becomes the unpleasant duty of the physician to so consider it. It is this type of growth that is so frequently mistaken for lupus, but the history of its not having begun so early in life and the absence of the so-called apple-jelly nodules seen in lupus vulgaris through a glass pressed over the lesion would rule out the latter.

89. **Tonsil Operation and Soft Palate and Voice.**—The causes for the belief that the removal of the tonsils in some way results in an impairment of the voice, are discussed by Hudson-Makuen. He shows that normal tonsils are in no way prejudicial to phonation, but, on the contrary, they may be helpful both in directing the action of the neighboring muscles and in modifying the resonance of the oral cavity. Hypertrophied tonsils, on the other hand, are distinctly prejudicial to phonation, because they interfere with the action of the muscles, they deflect the vibrating column of breath, and impair the normal resonance of the oral cavity. Degenerate tonsils are prejudicial to phonation primarily because they are prejudicial to health, and secondarily, because they interfere with the action of important vocal organs, by setting up a catarrhal condition in the oropharynx, which results in hypertrophy of the faucial pillars, the plica and the capsule, and in numerous inflammatory adhesions binding all these parts together in one conglomerate mass. The two important indications for the tonsil operation are, to remove foci of infection and to increase or restore the functional efficiency of the respiratory, phonatory and articulatory organs; and the operation that fails to meet the requirements of these two indications is more or less of a failure. The tonsil that requires removal is always prejudicial to vocal excellence. The author is firm in his claim that the popular belief that the removal of tonsils is injurious to the voice is well founded, and it is due in large measure to careless or bad surgery.

97. **Chronic Appendicitis.**—In five cases cited by Jacobson the early history has always been indefinite whether the symptoms have been referable to the stomach, duodenum, gall-bladder or the large bowel, and a period varying from one year to several years has elapsed before any evidence strongly suggesting appendicular disturbance has manifested itself. However, in the end, close analysis of the symptoms and repeated examinations of the abdomen have warranted each time the diagnosis of chronic appendicitis. Jacobson emphasizes that it is essential to investigate these cases thoroughly and to exclude all other pathologic conditions before determining to remove the appendix.

98. **Typhoid Bacillus Cholecystitis.**—Holmes reports a case of typhoid bacillus cholecystitis without typhoid fever or gall-stones. He says that typhoid bacillus cholecystitis is an invariable attendant on typhoid, but clinical (obstructive) cholecystitis occurs only when the cystic duct is obstructed. The gall-bladder often retains the infection long after the typhoid septicemia and typhoid enteritis have passed away, and then the typhoid bacilli may, by use of cholagogues, be found in the stools. The fate of a typhoid bacillus cholecystitis is so uncertain and so surrounded with danger that the fear of a surgical operation in the course or at the beginning of typhoid should not be given too much weight. The cholecystostomy should be performed promptly and quickly with the minimum of anesthetic and the minimum of traumatism. No attempt should be made during typhoid to remove stones from the cystic duct. A later cholecystectomy will rarely be necessary.

105. **Relative Frequency of Different Diseases Prevalent in Boston.**—In a hospital population of about 8,000 males over 18 years old, all of whom were carefully questioned by Cabot, 35 per cent. give a history of gonorrhea, and 11 per cent. a history of syphilis, at some period of their lives. These histories and the resulting percentages are believed to represent approximately the truth about an average sample of Boston's adult males. The Americans, Irish, English and Italians have about the same amount of both these venereal diseases. The Jews have about one-third as much syphilis and one-half as much gonorrhea as the other races. The history of an excessive consumption of alcohol was obtained in 32 per cent. of 8,356 patients questioned. The Jews show the smallest amount of alcoholism—the "Americans" the highest percentage of total abstainers. About one-fourth of all the 7,186 males who were questioned gave a history of using an excess of tobacco. The Italians appear to use rather less than the other races but the racial differences are less marked as regards tobacco than as regards alcohol and venereal disease. The statistics relating to alcohol and tobacco are regarded as an indication of the habits of a fair sample of Boston's population. Acute nephritis, chlorosis and sunstroke would appear (on the face of the records) to be decreasing. This decrease is shown by analysis, however, to be in all probability fallacious. Pyogenic infections are more than twice as numerous as any other known infection (tuberculosis included). Three Boston hospitals treated 6,892 cases of syphilis and only 4,819 of gonorrhea in the years 1903-1910 inclusive.

106. **Prostatic Concretions and Calculi.**—Three cases are reported by Lund. The lesson he would draw from these cases is that prostatic concretions are frequently associated with infiltration of the prostate, which makes a small, fibrous organ feel larger than it really is by rectal examination and may lead to the suspicion of malignant disease.

110. **Abdominal Pain from Anteroposterior Curvature.**—Rogers reports two cases in support of his claim that an anteroposterior spinal curvature may be the cause of abdominal pain simulating appendicitis, kidney disease, etc. In these two cases correction of the deformity gave relief from the pain.

113. **Chronic Acetanilid Poisoning.**—A study of the cases recorded in the literature and personal observation have convinced Gordinier that the ingestion over a considerable period of time of acetanilid or related coal-tar products is productive of a definite symptom-complex, which is highly suggestive, if not absolutely diagnostic of poisoning by this group. The subjective symptoms are great general weakness, nervous excitability, insomnia, loss of appetite, digestive disturbances, palpitation, dyspnea, numbness and weakness of the extremities, pain in the region of the liver and spleen and faint

attacks. The chief objective symptom is cyanosis, which is often extreme but usually fluctuating in intensity, accompanied by marked pallor of the mucous surfaces and without clubbing of the fingers. The blood changes are quite characteristic and due to the destructive action of a hemolytic poison circulating in the blood stream, which produces a secondary anemia variable in degree. The erythrocytes are diminished in number, they often present nucleated forms, show granular stippling, stain poorly and are variable in size and form. There is usually a moderate leukocytosis of the polymorphonuclear variety, and there is often a relative increase of the lymphocytes. The appearance of the blood as it stands on the finger tip or the ear is very suggestive; it is either of a bluish-black color or chocolate in appearance. The coloration of the plasma renders the estimation of the hemoglobin quite difficult.

The spleen has been found enlarged in most of the well-observed cases, and it is usually tender both on palpation and percussion. The liver is slightly increased in size and is also tender on pressure. The heart is usually found enlarged, the transverse diameter being increased and the apex beat being displaced downward and outward. The heart sounds are feeble, and adventitious murmurs are frequent; systolic, mitral and tricuspid murmurs are common, as are basic systolic murmurs. These murmurs are probably dynamic in origin and due to the loss of tonicity of the heart muscle, as they disappear *pari passu* with the diminution in size of the heart and improvement of the blood on the withdrawal of the acetanilid. The mitral and tricuspid murmurs are, doubtless, caused by relative leakage, while the basic murmurs are hemic in origin. The urine is usually dark brown or black in color and gives the characteristic indophenol reaction. It may contain blood pigments in the form of methemoglobin or hematrophorphorin; bilirubin is common; glycuronates may be present. It is interesting to note that the ratio of the sulphates has been found reversed. In Gordinier's first case, the ratio being 16 to 1, only a comparatively few milligrams of the oxidized sulphur being eliminated in the form of inorganic sulphates. Dextrose was found in both of his cases, and probably exists in small amounts in most cases. Gordinier *has been unable to find any mention in the literature of trophic* changes in the way of ulcerations of the skin such as occurred in one of his cases. That these ulcerations were due to the effects of acetanilid seems probable, as most other causes could be excluded.

114. **Radical Cure of Hydrocele.**—The method used by Whitney consists of the insertion of sterile catgut into the cavity of the tunica vaginalis. It is less toxic than phenol, less painful than iodin and more certain than either of them. By it an inflammation of the sac is immediately produced and as the fluid resulting from this is slowly absorbed, an adhesion of the walls occurs with obliteration of the sac and a permanent cure of the disease.

116. **Compression Myelitis by Aneurysm in Tabetic.**—A middle-aged colored man with admitted history of early syphilis suffered for two years with cramp-like pains, mostly in the limbs. For less than a month sensory disturbances were present, at first numbness, later anesthesia below nipples; also recently loss of sphincter control. On examination the pupils were found to be unequal and to react sluggishly to light, and knee-jerks absent. A large, pulsating aneurysm in the back readily explained the anesthesia and paralysis of the lower limb, but did not explain flaccidity and loss of reflexes.

At autopsy the aneurysm was found to have eroded parts of four vertebræ and to compress the cord in the upper dorsal region to such an extent as to cause severe distortion. The pressure exerted caused the degenerations expected—Gower's and the direct cerebellar tracts upward, pyramidal tracts downward—except in one instance, namely, the posterior columns which were free from evidence of recent degeneration. Referring to Weigert sections it was evident that the man had pretty well-marked posterior tract degeneration of long standing; there was not a section from sacral to cervical but which showed marked posterior root atrophy. On this field of posterior column fibers no fresh degeneration appeared.

Ayer believes that in this case there were evidently two cord lesions, one of ancient date, tabetiform in character; the other, acute and caused by pressure of the aneurysm. The older process probably accounted for the symptoms of the previous two years, the pressure effects, for the culminating and serious symptoms of paralysis and anesthesia which so overshadowed the older disease.

119. **Case of Anaphylaxis.**—The patient received 3,000 units diphtheria antitoxin subcutaneously in the abdominal wall. There was no bleeding through the needle. Antitoxin was administered with the patient in a recumbent posture. At the end of five minutes he felt well and arose, but began to sneeze continuously and his nostrils became obstructed. He soon grew dizzy and complained that everything was growing dark. About fifteen minutes after receiving the injection he was cyanotic and his inspiration was noisy and difficult. Preparations were made for intubation of the larynx, if the necessity should arise. He raised himself on one elbow in the bed, laboring for breath, with frequent cough and expectoration of pinkish serum. His face, especially about the eyes, was swollen. The conjunctivæ were injected; the skin was cold and covered with perspiration, and the pulse was absent in both radial and brachial arteries—even the apex beat not being palpable. A hypodermic injection of atropin sulphate, gr. 1/100, and strychnin sulphate, gr. 1/30, was administered. In a few moments the respiration became more quiet and at the end of fifteen minutes the patient sank back to the recumbent posture and the serous expectoration ceased. At this time the patient had an urgent desire to defecate and passed a large, brown semiformed stool. Twenty-five minutes after the injection of antitoxin the radial pulse became barely palpable. The blood-pressure, however, was too low to be recorded with the sphygmomanometer. The skin all over was brightly flushed. The tongue was swollen, its edges showing the impressions of the teeth; the soft palate and uvulva were edematous and their vessels were injected.

Two hours after the serum injection the patient drank a pint of water which he promptly vomited. The regurgitated liquid was pink and frothy. During the efforts at vomiting the pulse-rate sped up to 150 but afterward dropped to 96. At three and one-half hours the arterial pressure was about 105 m.m. The patient went quietly to sleep about four hours after the antitoxin injection, his symptoms having now disappeared. Examination of the first urine voided after the antitoxin injection showed a specific gravity of 1.032, neutral reaction, no albumin, a trace of glucose. No further symptoms developed until nine days later, when a general urticaria appeared with much edema of the eye-lids. This continued three days and then disappeared.

139. Mineral Salts in Metabolism of Infants.—Hoobler discusses the part which mineral salts play in carrying on the physiologic functions of the body and in what manner they contribute to the various pathologic processes to which the infant and young child are subject. He records fully his results in a series of metabolism studies made on a perfectly healthy infant, 9 months old, who had been fed on cow's milk from the time of birth. Briefly, he found that salts are necessary to maintain life. They are best absorbed and utilized when in organic combination with food-stuffs. There are marked differences in the salt content of mother's and cow's milk which should be considered in artificial feeding. Certain pathologic conditions arise in which certain of the salts are not absorbed, even though in abundance in the food. In certain other pathologic conditions salts are actually withdrawn from the body to such an extent as to impoverish the organism and produce grave disturbances of nutrition. The various salts, with the exception of iron, are present in sufficient quantities and proper proportions in mother's milk. In most of the dilutions of cow's milk there is an excess of salts which may be neglected in feeding normal infants, but which plays an important rôle in the feeding of children already suffering from nutritional disturbances. The conditions under which the salt content of feedings should be altered and in just what degree each or all should be varied, are still unsolved problems.

1. Present Position of Medical Profession.—Speaking of medical education, Saundby says, in his presidential address before the British Medical Association, that it should be possible to make the curriculum five years in a medical school after preliminary science has been passed, and so adequate time be obtained for those subjects which can be learned only in a medical school and in a hospital. Though there is still much in the modern arrangements for medical education which falls short of our desires, there has been a vast improvement in the organization of medical teaching, in the equipment of medical schools, and in their methods of instruction. Medical education in England has always had its feet firmly planted on the solid foundation of hospital work, but it was deficient in academic opportunities as compared with the schools of Scotland and the Continent. The hospitals have provided abundant clinical material, and many subordinate appointments of incalculable value for the training of practitioners, but the scientific needs of students are but poorly supplied in them. During the last ten years this has been to some extent remedied by the better equipment of the medical schools, mainly by the self-sacrifice of the senior teachers, who have surrendered the greater part of their scanty emoluments for this purpose; laboratories have been started in all schools, and in some hospitals it has been realized that it is not enough to possess good accommodation for the care and comfort of the sick, but that adequate means must also be provided for the study of their diseases by good laboratories with a sufficient paid staff. Saundby asks that hospital authorities take a broader view of their duties and realize that in the end the interest of the patients will be best served by spending more money on the scientific equipment of these institutions. The function of voluntary hospitals, medicine and the state and the national insurance bill are also considered in this paper.

2. Mistakes.—This is the address in medicine delivered at the recent annual meeting of the British Medical Association. Bramwell points out that there are mistakes of various kinds. There are the bad mistakes, which show incapacity to make the most ordinary observations, gross ignorance, or inexcusable carelessness; and there are the slight mistakes—they perhaps should hardly be called mistakes—such as erroneous conclusions with regard to the significance of certain facts or groups of facts. There are mistakes of omission and mistakes of commission, mistakes due to incomplete, inaccurate, or erroneous observation, mistakes due to hasty or illogical conclusions. There are mistakes which as regards their results are unimportant; and mistakes which, either to the practitioner who makes them, to the patient whose case is wrongly diagnosed, or to the public at large, are of great importance, since they may entail very disastrous consequences. Mistakes due to imperfect knowledge, to want of clinical experience, to erroneous observation, to inability to observe correctly, are most common in the early years of one's practice. In the case of experienced practitioners, hurry, and the incomplete examination of patients due to hurry, and hasty conclusions are probably by far the most common causes of errors in diagnosis. Physiognomonic diagnoses are apt to be erroneous. Mistakes are not infrequently due to the fact that the information secured from third parties is insufficient, inaccurate, or misleading. Before a disease is described as a distinct clinical and pathologic entity; typical and characteristic cases, which a few years later are easily diagnosed, are mistaken for other conditions. Mistakes due to erroneous deductions and illogical conclusions are very common. Even those men in whom the judicial faculties are most highly cultivated often fail to draw the same conclusions from the same facts.

Mistakes in diagnosis often occur because undue importance is given to some symptom or physical sign which is present. Mistakes are sometimes due to too little importance being attached to some fact or facts. Errors in diagnosis are often due to the fact that one's judgment is warped or biased from some cause or another. Most of us probably know how difficult it is to diagnose and treat illness in one's self or in members of one's own family. One's judgment is upset by anxiety and fear; all sorts of terrible possibilities occur to the mind and prevent one taking a cool and level-headed view of the case. On the other hand, one occasionally sees the exact reverse of this picture—a medical man the subject of advanced organic disease ignoring it or making light of it, and of the symptoms which it produces, in the most extraordinary way. One's judgment is apt to become biased in favor of some particular theory or idea, and under such circumstances, one sees everything in the light of that idea. Erroneous therapeutic conclusions, based on too limited a number of observations, are common.

3. Progress in Surgery.—Lloyd reviews the advances made in surgery, speaking more particularly of exploratory operations, kidney and stomach surgery, appendicitis, colostomy, cecostomy, prostatectomy and herniotomy. Speaking of gastric surgery he says that precision in the diagnosis of many stomach diseases can be secured only by exploratory incision, and that earlier resort to this procedure in many cases is very desirable. When pyloric obstruction is present, as eviattacks. The chief objective symptom is cyanosis, which is often extreme but usually fluctuating in intensity, accompanied by marked pallor of the mucous surfaces and without clubbing of the fingers. The blood changes are quite characteristic and due to the destructive action of a hemolytic poison circulating in the blood stream, which produces a secondary anemia variable in degree. The erythrocytes are diminished in number, they often present nucleated forms, show granular stippling, stain poorly and are variable in size and form. There is usually a moderate leukocytosis of the polymorphonuclear variety, and there is often a relative increase of the lymphocytes. The appearance of the blood as it stands on the finger tip or the ear is very suggestive; it is either of a bluish-black color or chocolate in appearance. The coloration of the plasma renders the estimation of the hemoglobin quite difficult.

The spleen has been found enlarged in most of the well-observed cases, and it is usually tender both on palpation and percussion. The liver is slightly increased in size and is also tender on pressure. The heart is usually found enlarged, the transverse diameter being increased and the apex beat being displaced downward and outward. The heart sounds are feeble, and adventitious murmurs are frequent; systolic, mitral and tricuspid murmurs are common, as are basic systolic murmurs. These murmurs are probably dynamic in origin and due to the loss of tonicity of the heart muscle, as they disappear *pari passu* with the diminution in size of the heart and improvement of the blood on the withdrawal of the acetanilid. The mitral and tricuspid murmurs are, doubtless, caused by relative leakage, while the basic murmurs are hemic in origin. The urine is usually dark brown or black in color and gives the characteristic indophenol reaction. It may contain blood pigments in the form of methemoglobin or hematrophorphorin; bilirubin is common; glycuronates may be present. It is interesting to note that the ratio of the sulphates has been found reversed. In Gordinier's first case, the ratio being 16 to 1, only a comparatively few milligrams of the oxidized sulphur being eliminated in the form of inorganic sulphates. Dextrose was found in both of his cases, and probably exists in small amounts in most cases. Gordinier has been unable to find any mention in the literature of trophic changes in the way of ulcerations of the skin such as occurred in one of his cases. That these ulcerations were due to the effects of acetanilid seems probable, as most other causes could be excluded.

114. **Radical Cure of Hydrocele.**—The method used by Whitney consists of the insertion of sterile catgut into the cavity of the tunica vaginalis. It is less toxic than phenol, less painful than iodin and more certain than either of them. By it an inflammation of the sac is immediately produced and as the fluid resulting from this is slowly absorbed, an adhesion of the walls occurs with obliteration of the sac and a permanent cure of the disease.

116. **Compression Myelitis by Aneurysm in Tabetic.**—A middle-aged colored man with admitted history of early syphilis suffered for two years with cramp-like pains, mostly in the limbs. For less than a month sensory disturbances were present, at first numbness, later anesthesia below nipples; also recently loss of sphincter control. On examination the pupils were found to be unequal and to react sluggishly to light, and knee-jerks absent. A large, pulsating aneurysm in the back readily explained the anesthesia and paralysis of the lower limb, but did not explain flaccidity and loss of reflexes.

At autopsy the aneurysm was found to have eroded parts of four vertebræ and to compress the cord in the upper dorsal region to such an extent as to cause severe distortion. The pressure exerted caused the degenerations expected—Gower's and the direct cerebellar tracts upward, pyramidal tracts downward—except in one instance, namely, the posterior columns which were free from evidence of recent degeneration. Referring to Weigert sections it was evident that the man had pretty well-marked posterior tract degeneration of long standing; there was not a section from sacral to cervical but which showed marked posterior root atrophy. On this field of posterior column fibers no fresh degeneration appeared.

Ayer believes that in this case there were evidently two cord lesions, one of ancient date, tabetiform in character; the other, acute and caused by pressure of the aneurysm. The older process probably accounted for the symptoms of the previous two years, the pressure effects, for the culminating and serious symptoms of paralysis and anesthesia which so overshadowed the older disease.

119. **Case of Anaphylaxis.**—The patient received 3,000 units diphtheria antitoxin subcutaneously in the abdominal wall. There was no bleeding through the needle. Antitoxin was administered with the patient in a recumbent posture. At the end of five minutes he felt well and arose, but began to sneeze continuously and his nostrils became obstructed. He soon grew dizzy and complained that everything was growing dark. About fifteen minutes after receiving the injection he was cyanotic and his inspiration was noisy and difficult. Preparations were made for intubation of the larynx, if the necessity should arise. He raised himself on one elbow in the bed, laboring for breath, with frequent cough and expectoration of pinkish serum. His face, especially about the eyes, was swollen. The conjunctivæ were injected; the skin was cold and covered with perspiration, and the pulse was absent in both radial and brachial arteries—even the apex beat not being palpable. A hypodermic injection of atropin sulphate, gr. 1/100, and strychnin sulphate, gr. 1/30, was administered. In a few moments the respiration became more quiet and at the end of fifteen minutes the patient sank back to the recumbent posture and the serous expectoration ceased. At this time the patient had an urgent desire to defecate and passed a large, brown semiformed stool. Twenty-five minutes after the injection of antitoxin the radial pulse became barely palpable. The blood-pressure, however, was too low to be recorded with the sphygmomanometer. The skin all over was brightly flushed. The tongue was swollen, its edges showing the impressions of the teeth; the soft palate and uvulva were edematous and their vessels were injected.

Two hours after the serum injection the patient drank a pint of water which he promptly vomited. The regurgitated liquid was pink and frothy. During the efforts at vomiting the pulse-rate sped up to 150 but afterward dropped to 96. At three and one-half hours the arterial pressure was about 105 m.m. The patient went quietly to sleep about four hours after the antitoxin injection, his symptoms having now disappeared. Examination of the first urine voided after the antitoxin injection showed a specific gravity of 1.032, neutral reaction, no albumin, a trace of glucose. No further symptoms developed until nine days later, when a general urticaria appeared with much edema of the eye-lids. This continued three days and then disappeared.

impulse, respectively. The radial pulse was markedly alternating; but there was no evidence in the cardiograms of variations in strength of the ventricular contraction. (b) In the other case pulsation was recorded from the clinical apex-beat, and also from the fourth left intercostal space about 1½ inches from the left edge of the sternum. The cardiogram from both situations had the characters of left ventricular pulsation; that obtained from the fifth space at no time showed alternation in force. The cardiogram from the fourth intercostal space continuously alternated, except for brief periods.

The relationship between the alternating beats of the cardiogram and those of the radial pulse were not constant, the height of the respective waves being at times opposed, at others similar; at others, again, alternation was present in the heart-beat curve, whilst that of the radial pulse was equal; the reverse relationship occurred. Alternation was often pronounced in records of the jugular pulsation of this patient; invariably the larger wave corresponded to the higher wave of the radial pulse. In curves having character of right ventricular pulsation no evidence of alternation was present at any time. No variation in the intensity, pitch or duration of the heart-sounds or murmurs coincident with alternation of the pulse was detected in any case. While the observations lend some support to the view of Hering, that in alternate heart-beat a partial systole of the ventricle occurs, they also show that in alternating pulse it is not always possible, in clinical cases, to determine the fact of alternating heart action.

20. **Analysis of Gastric Contents.**—The investigations made by Panton and Tidy fall into two parts: the first deals with the routine examination of test-meals in a series of cases, the second consists of an inquiry into the various methods of examining test-meals and the meaning of the results obtained. In all 331 cases were examined: Carcinoma of stomach, 43 cases, operated 30. Gastric ulcer, 87 cases, operated 49. Duodenal ulcer, 36 cases, operated 21. Other gastric cases not operated, 62. Various conditions, 103 cases, operated 36. The results obtained follow: In normal gastric contents Günzberg's reaction is positive, free hydrochloric acid varies between 0.08 and 0.12, and the acidity lies between 40 and 50. In carcinoma of the stomach Günzberg's reaction is nearly always negative, i. e., free hydrochloric acid is absent. The average of the total acidity is 26. Some dimethyl acidity is often present. In the rare cases in which carcinoma is grafted on a simple ulcer, free hydrochloric acid is usually present, and the total acidity may be normal or even above normal. Thus, in these cases, the analysis often resembles that found in simple gastric ulcer. In simple gastric ulcer Günzberg's reaction is positive, the average of the free hydrochloric acid is 0.13 and the total acidity, 58. Free hydrochloric acid may be absent after a severe hemorrhage or after a previous gastrojejunostomy. In duodenal ulcer the average of the free hydrochloric acid is 0.17, and the total acidity, 69. Free hydrochloric acid is usually absent in cases of achylia gastrica, chronic alcoholic gastritis, severe anemia, chronic pulmonary tuberculosis, and in some forms of chronic dyspepsia. In these latter cases relief of gastric symptoms usually follows treatment by acids. Cases of hyperchlorhydria are commonly relieved by alkalies. It is not suggested by the authors that the diagnosis and treatment of gastric cases should depend on the result of test-meals alone, but they find that the simple analysis described affords very reliable information when taken in conjunction with clinical observation, and particularly with a carefully taken history.

21. **Systolic Pressure.**—The conclusions which Findlay draws from his study of well and sick children are, briefly: During childhood and youth the systolic arterial pressure is fairly uniform at different points of the circulation. In adult life the peripheral systolic pressure is lower than the central, and the difference between them increases with age. The difference greater than normal between the central and peripheral systolic pressures in cases of hypertension—from disease or experimentally induced—supports the idea that the behavior of the pressure and its variations depends on changes in the elasticity of the vessel wall.

22. **Function of A-V Bundle.**—The first case cited by the authors was one of Adams-Stokes syndrome with chronic bradycardia for many months, interrupted by short paroxysms of tachycardia. The post-mortem microscopic examination of the heart showed a destruction completely across the chief trunk of the a-v bundle. The heart was enlarged throughout (weight 590 gm.), the mitral valve calcified and the mitral ostium somewhat contracted. The calcareous infiltrations were continued into the septum membranaceum; on the right side this calcification could be seen as a projecting knot, the size of a pea and calcified right through, occupying the front part of the septum membranaceum. Also the aortic valves, especially the left were calcified so that the calcareous encrustations from the mitral valve and septum membranaceum were continued directly to the aortic valves. Both of the coronaries were calcified, but in no place obliterated or contracted. Microscopically, the muscles of the heart appeared normal, excepting certain small fibrous scars in the left ventricle. The macroscopic appearance of the calcareous knot and its situation alone made it highly probable that the main trunk of the a-v bundle must be damaged by the calcareous masses to a greater or lesser extent. The microscopic examination also showed that the main trunk of the a-v bundle had disappeared entirely, leaving not a trace of its normal tissue in the great calcareous knot. The authors assume that the relationship between auricle and ventricle along the a-v bundle must have been quite broken for a long time before death, and when also all the signs of a complete block have long been present, there occur attacks of great frequency of the pulse. The tracings from the last weeks of the patient's [illegible] show that the stimulus conduction from auricle to [illegible] reflex must have oeen to some extent restored, thoug[illegible] in two other the post-mortem a little later makes it ma bradycardia no that the main trunk of the a-v bundle mumption of injury to say, cut across by the large calcareous kiopment of jaun-

In the second case there was a normal urine. In itself, strongly pronounced degenerative neuritis ndicate operative nerves. At the post-mortem exam in prosthesis, he thinks; if to be hypertrophied, dilated and to [illegible]ntion of bile salts or with fat; it weighed 510 gm. The subperica[illegible], the injury highly developed, especially over the right half of the[illegible] than where the muscles were also somewhat infiltrated with fat without showing any signs of fatty degeneration. Incipient arteriosclerotic changes in the aorta were present. The coronary arteries were normal. An embolus was found in the right pulmonary artery, with an incipient hemorrhagic infarct in the lung. The other organs were found in all essentials normal. The microscopic examination of the a-v bundle showed that it was mixed with fatty tissue with large fat cells, perhaps to a little higher degree than is found on an average; but not outside the normal limits. The fatty tissue was found especially in the main trunk and also in the left branch. The a-v bundle was also somewhat hyperemic (a post-mortem phenomenon), but not especially strongly marked. On the whole, the a-v bundle presented no clear pathologic alterations. In both vagus nerves there were found very important anatomic changes. In unstained preparations from the upper part of the nerves black drops of fat could be seen around the nerve. In sections in which the nerve was longitudinally cut, the fibers were to a large extent brownish-black to black in color. Such black fibers were found partly through long stretches of the nerve, and they were on the whole rather homogeneous, although in places it gave the impression of a kind of accumulation of small granules of different sizes. In places where the section had been made across the nerve, there were, in addition to swollen black nerve fibers, a similar number of more yellowish normal fibers. The middle portion of the neck vagus showed on the whole the same aspect as described above, but the black parts of the nerve fibers were seen to be more extensive, so that the majority of the nerve fibers are black; the black round or cylindric formations were seen on closer inspection to be formed by numerous small granules or fragments. In sections from the lower portion of the nerve (about where the cardiac branches come off), extensive black cylindrical formations were seen, consisting of extremely fine, small, black granules, denced by periodic vomiting, treatment by posterior gastrostomy is eminently and uniformly satisfactory. Pain in such patients may be absent altogether. When vomiting is absent or only occasional, and pain is the symptom for which a patient seeks relief, gastro-enterostomy has its failures. Acute ulcers of the stomach, except when perforating, do not demand surgical treatment; chronic ulcers, on the other hand, do; but what that treatment is to be he is uncertain. Some should be excised, some are cured by gastro-enterostomy, some should be infolded, and possibly some should be left alone by the surgeon. Operations for gastric carcinoma are at the present time unsatisfactory, probably owing to their nonearly recognition. Dilated stomachs, in the absence of associated lesions such as pyloric narrowing or ulceration, may be left unoperated on. Gastric hemorrhages are not to be dealt with satisfactorily by surgical operation. They do better in the hands of the physician. Duodenal hemorrhages, too, are not readily amenable to surgical treatment. Gastro-enterostomy does not meet their urgent indications, although it may contribute to the healing of the ulcers in which the bleeding originates. Chronic duodenal ulcer is a pathologic fact; it is no mere surgical apparition as is sometimes suggested. Its frequency in adult males is remarkable; its diagnosis prior to exploration is highly probable, but by no means sure; its recognition at the time of operation is certain, and its relief by operation is most satisfactory. In Birmingham cancer of the stomach does not appear so often as a sequel of chronic ulceration as it is said to do in many other places. The majority of patients with cancer of the stomach give no account whatever of long-standing or of past indigestions. It appears usually as a primary indigestion in the middle-aged or elderly, and in all such patients Lloyd agrees that by the failure of medical treatment quickly to relieve such indigestion, a suspicion of cancer should be aroused and an exploratory operation at once performed.

As for herniotomy, he says that the most important step of the operation has to do with the sac of the hernia. The neck of the sac should not be ligatured, but the peritoneum beyond the neck, and when this has been done and cut across below the ligature, it matters little whether the sac is removed or not. The closure of rings and canals is said to be a matter of secondary importance; in Lloyd's opinion it should always be done, except in the inguinal hernias of very young children, and well done, too. Lloyd is performing regularly both suprapubic and perineal prostatectomy, and finds that each has its merits, and that neither can claim to be the better for all cases. The suprapubic operative mortality is rather the higher in his hands, probably because the more serious cases have been dealt with by this method. The after-results of both operations are then about the same. Prostatectomy for carcinoma and tubercle has been disappointing in his hands.

4. **Treatment of Fracture of Patella.**—The treatment employed by Maclachlan is as follows: First, a mold is made of the sound knee by taking poroplastic material, 1½ feet long by 6 inches broad, which is softened in boiling water, and then firmly placed on the sound knee. In this way a perfect mold of the knee-cap is taken; this is used as a splint for the fractured patella, the fragments being viced in the cap of the splint. A little cotton-wool is placed in the cap and sufficient to pad the rest of the splint, which extends above and below the knee-joint. Prior to fixing the splint the fragments are strapped into position by adhesive plaster, and longer strips are placed immediately above and below the patella, and drawn in contrary directions to pull the upper and lower fragments together. Lastly, a plaster-of-Paris bandage is put over all. In three weeks the plaster-of-Paris bandage is taken off. The splint is kept on for two weeks, passive exercises begun, and a knee-cap worn for two months, when it is discarded.

12. **The Appendix.**—Jones advises that the appendix should be examined in every case of celiotomy for adnexal disease. This equally applies to the left adnexa as to the right. When the abdomen is opened for a grave appendix trouble, the adnexa should be examined. The appendix should be removed in every instance in which any abnormality or disease is found or if it be of unusual length, also if from the character of the operation there is a probability of further adhesions forming which may involve the appendix. The severity of the operation, however, will always have to be taken into account, and the influence its prolongation may have in lessening the chances of the patient's recovery.

14. **Ovariotomy and Cesarean Section.**—The operation in this case was performed for the ovarian disease which had become very troublesome. The duration of the pregnancy could not be determined because of the size of the ovarian tumor. The ovarian cyst was tapped and removed and then the section was done and a viable fetus about 8 months old was extracted. Both mother and child lived.

18. **Etiology of Auricular Fibrillation.**—Rheumatic or choreic disease preceded auricular fibrillation in 56.6 per cent. of the cases examined by Lea. The most frequent lesion to which it gave rise being mitral stenosis (43.6 per cent. of cases with rheumatic history). Non-rheumatic cases presented auricular fibrillation in 43.4 per cent., the most frequent cardiac lesion being cardio- or arteriosclerosis, 57.1 per cent. The age incidence of mitral valve disease, with or without preceding rheumatism, was 38.2 years; the age incidence of cardiosclerosis was 53.9 years in rheumatic cases, 56.9 years in non-rheumatic. Females were more frequently subject to valvular disease than males in the proportion of 16 to 10; males were more subject to arterio- or cardiosclerosis, 15 to 8. Of all cases of auricular fibrillation, 32.8 per cent. occurred in cardiosclerosis, 31.3 per cent. in mitral stenosis, and 23.8 per cent. in cardiac dilatation. Influenza was noted as having occurred in 39.3 per cent. of non-rheumatic cases. Electrocardiographic records confirmed, in all cases examined, the polygraphic records.

19. **Heart-Beat and Pulsus Alternans.**—In all cases but one observed by Windle no alternation was present in records taken from the clinical apex beat, while in all disparity in force of alternate radial pulses was decided, and at times extreme. In the exceptional case the stronger beat of the heart-curve coincided with the weaker of the pulse. It is suggested that this anomaly is explicable on the assumption that the musculature of the ventricle producing the apex beat is not a part of that which drives the blood out of the left ventricle, otherwise it is inexplicable that the stronger beat of the ventricle should cause the weaker pulse, or that ventricular contractions equal in strength, beat by beat, should cause an alternating pulse. In two patients the heart's pulsation was recorded from two distinct areas: (a) In one case the cardiograms have the character of a left and right ventricular

impulse, respectively. The radial pulse was markedly alternating; but there was no evidence in the cardiograms of variations in strength of the ventricular contraction. (b) In the other case pulsation was recorded from the clinical apex-beat, and also from the fourth left intercostal space about 1½ inches from the left edge of the sternum. The cardiogram from both situations had the characters of left ventricular pulsation; that obtained from the fifth space at no time showed alternation in force. The cardiogram from the fourth intercostal space continuously alternated, except for brief periods.

The relationship between the alternating beats of the cardiogram and those of the radial pulse were not constant, the height of the respective waves being at times opposed, at others similar; at others, again, alternation was present in the heart-beat curve, whilst that of the radial pulse was equal; the reverse relationship occurred. Alternation was often pronounced in records of the jugular pulsation of this patient; invariably the larger wave corresponded to the higher wave of the radial pulse. In curves having character of right ventricular pulsation no evidence of alternation was present at any time. No variation in the intensity, pitch or duration of the heart-sounds or murmurs coincident with alternation of the pulse was detected in any case. While the observations lend some support to the view of Hering, that in alternate heart-beat a partial systole of the ventricle occurs, they also show that in alternating pulse it is not always possible, in clinical cases, to determine the fact of alternating heart action.

20. **Analysis of Gastric Contents.**—The investigations made by Panton and Tidy fall into two parts: the first deals with the routine examination of test-meals in a series of cases, the second consists of an inquiry into the various methods of examining test-meals and the meaning of the results obtained. In all 331 cases were examined: Carcinoma of stomach, 43 cases, operated 30. Gastric ulcer, 87 cases, operated 49. Duodenal ulcer, 36 cases, operated 21. Other gastric cases not operated, 62. Various conditions, 103 cases, operated 36. The results obtained follow: In normal gastric contents Günzberg's reaction is positive, free hydrochloric acid varies between 0.08 and 0.12, and the acidity lies between 40 and 50. In carcinoma of the stomach Günzberg's reaction is nearly always negative, i. e., free hydrochloric acid is absent. The average of the total acidity is 26. Some dimethyl acidity is often present. In the rare cases in which carcinoma is grafted on a simple ulcer, free hydrochloric acid is usually present, and the total acidity may be normal or even above normal. Thus, in these cases, the analysis often resembles that found in simple gastric ulcer. In simple gastric ulcer Günzberg's reaction is positive, the average of the free hydrochloric acid is 0.13 and the total acidity, 58. Free hydrochloric acid may be absent after a severe hemorrhage or after a previous gastrojejunostomy. In duodenal ulcer the average of the free hydrochloric acid is 0.17, and the total acidity, 69. Free hydrochloric acid is usually absent in cases of achylia gastrica, chronic alcoholic gastritis, severe anemia, chronic pulmonary tuberculosis, and in some forms of chronic dyspepsia. In these latter cases relief of gastric symptoms usually follows treatment by acids. Cases of hyperchlorhydria are commonly relieved by alkalies. It is not suggested by the authors that the diagnosis and treatment of gastric cases should depend on the result of test-meals alone, but they find that the simple analysis described affords very reliable information when taken in conjunction with clinical observation, and particularly with a carefully taken history.

21. **Systolic Pressure.**—The conclusions which Findlay draws from his study of well and sick children are, briefly: During childhood and youth the systolic arterial pressure is fairly uniform at different points of the circulation. In adult life the peripheral systolic pressure is lower than the central, and the difference between them increases with age. The difference greater than normal between the central and peripheral systolic pressures in cases of hypertension—from disease or experimentally induced—supports the idea that the behavior of the pressure and its variations depends on changes in the elasticity of the vessel wall.

22. **Function of A-V Bundle.**—The first case cited by the authors was one of Adams-Stokes syndrome with chronic bradycardia for many months, interrupted by short paroxysms of tachycardia. The post-mortem microscopic examination of the heart showed a destruction completely across the chief trunk of the a-v bundle. The heart was enlarged throughout (weight 590 gm.), the mitral valve calcified and the mitral ostium somewhat contracted. The calcareous infiltrations were continued into the septum membranaceum; on the right side this calcification could be seen as a projecting knot, the size of a pea and calcified right through, occupying the front part of the septum membranaceum. Also the aortic valves, especially the left were calcified so that the calcareous encrustations from the mitral valve and septum membranaceum were continued directly to the aortic valves. Both of the coronaries were calcified, but in no place obliterated or contracted. Microscopically, the muscles of the heart appeared normal, excepting certain small fibrous scars in the left ventricle. The macroscopic appearance of the calcareous knot and its situation alone made it highly probable that the main trunk of the a-v bundle must be damaged by the calcareous masses to a greater or lesser extent. The microscopic examination also showed that the main trunk of the a-v bundle had disappeared entirely, leaving not a trace of its normal tissue in the great calcareous knot. The authors assume that the relationship between auricle and ventricle along the a-v bundle must have been quite broken for a long time before death, and when also all the signs of a complete block have long been present, there occur attacks of great frequency of the pulse. The tracings from the last weeks of the patient's [illegible] show that the stimulus conduction from auricle to [illegible] reflex must have been to some extent restored, thoug[illegible] in two other the post-mortem a little later makes it m[illegible] bradycardia no that the main trunk of the a-v bundle m[illegible]umption of injury to say, cut across by the large calcareous k[illegible]opment of jaun-

In the second case there was a normal urine. In itself, strongly pronounced degenerative neuritis ndicate operative nerves. At the post-mortem exam in pro[illegible]thesis, he thinks; if to be hypertrophied, dilated and to [illegible]ntion of bile salts or with fat; it weighed 510 gm. The subperica[illegible] the injury highly developed, especially over the right half of th[illegible] than where the muscles were also somewhat infiltrated with fat without showing any signs of fatty degeneration. Incipient arteriosclerotic changes in the aorta were present. The coronary arteries were normal. An embolus was found in the right pulmonary artery, with an incipient hemorrhagic infarct in the lung. The other organs were found in all essentials normal. The microscopic examination of the a-v bundle showed that it was mixed with fatty tissue with large fat cells, perhaps to a little higher degree than is found on an average; but not outside the normal limits. The fatty tissue was found especially in the main trunk and also in the left branch. The a-v bundle was also somewhat hyperemic (a post-mortem phenomenon), but not especially strongly marked. On the whole, the a-v bundle presented no clear pathologic alterations. In both vagus nerves there were found very important anatomic changes. In unstained preparations from the upper part of the nerves black drops of fat could be seen around the nerve. In sections in which the nerve was longitudinally cut, the fibers were to a large extent brownish-black to black in color. Such black fibers were found partly through long stretches of the nerve, and they were on the whole rather homogeneous, although in places it gave the impression of a kind of accumulation of small granules of different sizes. In places where the section had been made across the nerve, there were, in addition to swollen black nerve fibers, a similar number of more yellowish normal fibers. The middle portion of the neck vagus showed on the whole the same aspect as described above, but the black parts of the nerve fibers were seen to be more extensive, so that the majority of the nerve fibers are black; the black round or cylindric formations were seen on closer inspection to be formed by numerous small granules or fragments. In sections from the lower portion of the nerve (about where the cardiac branches come off), extensive black cylindrical formations were seen, consisting of extremely fine, small, black granules, lying spread in the larger bundles. Examination of the right vagus showed the same appearance as that described for the left. In hematoxylin stained sections no signs of inflammation were to be seen. The right and left middle cervical sympathetic ganglion and the cardiac sympathetic ganglion, prepared in exactly the same manner as the vagus, showed nothing abnormal.

The medulla oblongata showed in the upper half of the fourth ventricle and in the lower half no degenerated nerve fibers. The ganglion cells at the bottom of the fourth ventricle, amongst which are the vagus nuclei, showed an extremely finely granulated grey-black coloration (lipochromate), but no signs of degeneration. The hypophysis showed its normal structure without any sign of inflammation or degeneration. The chief interest in this case lies in the fact that in all probability it must be regarded as a case of Adams-Stokes disease of vagal origin. The authors hold that the muscular (extra-fascicular) type of the disease of Adams-Stokes that is especially described by Pletnew and Nayago, has still to be proved in man.

34. **Traumatic Spondylitis.**—Imbert and Vial warn against the deceptive subsidence of symptoms after an accident involving the spine. After the first period of local pain and soreness, with possibly some paralysis of the sphincters and slight exaggeration of the leg reflexes, all the symptoms may subside and the patient may be apparently quite well for several weeks or months. But then the site of the contusion gradually grows painful again and girdle pains develop with incontinence or retention of urine, constipation or diarrhea, etc., and the patient stoops forward, the curvature of the spine being generally of the scoliotic type. Treatment should be along the same lines as for Pott's disease, striving to immobilize and relieve the spine of all weight-bearing. Reclining in the dorsal decubitus with a cushion under the lumbar region is indicated during the first stage, and also if the patient is seen at the onset of the third phase; the condition should be supervised with the Roentgen rays during the quiescent period if possible. The final outcome is generally ankylosis, and there may be industrial incapacity equivalent to 25 or 50 per cent. of the original wage. The characteristic feature of this form of injury of the spine, known as Kümmel-Verneuil's disease, is the period of latency preceding the development of the curvature.

35. **Digitalis and Heart-Block.**—Martinet presents arguments to sustain his assertion that digitalis is contra-indicated in case of partial heart-block while it may be indicated in total heart-block. In case of mitral stenosis, digitalis is contraindicated if the presystolic souffle is missing, the jugular or liver-pulse is synchronous with the cardiac systole, and the heart occasionally skips a beat, with a curve showing disturbance in conductibility.

36. **Treatment of Tuberculosis of the Kidney.**—Bernard discusses whether the progress realized in tuberculin treatment and other medical measures in the last fifteen years justifies reliance on medical measures alone in renal tuberculosis. His conclusions are that nephrectomy is still the one great reliance and medical measures come into their own only when operative measures are impracticable for any reason.

37. **Vaccine Therapy.**—Renaud prepares his vaccine from selected cultures of the bacillus of typhoid fever by emulsionizing a forty-eight-hour growth on gelose with physiologic salt solution in the proportion of 5 mg. of culture to the cubic centimeter. This emulsion is submitted to the action of the ultraviolet rays for thirty minutes, by which the bacteria are killed. He finds that animals, guinea-pigs or rabbits are immunized by moderate or large non-lethal doses more readily than by small doses. The inoculation entails no risk of infection and the result is the rapid establishment of an immunity with the appearance of antibodies in the serum. The author has used his vaccine in forty clinical cases, which he will report later.

38 *Sodium Chlorid as Factor in Edema Induced by Large Doses of Sodium Bicarbonate. F. Widal, A. Lemierre and Cotoni.

July 26, XXXI, No. 30, pp. 349-360

39 *Cleaning and Scraping the Uterus After Septic Abortion. R. De Bovis.

38. **Edema Following Large Doses of Sodium Bicarbonate.**—Widal, Lemierre and Cotoni describe some clinical experiences and experiments on normal persons which demonstrate that ingestion of sodium bicarbonate in large amounts checks the elimination of sodium chlorid. As the sodium chlorid is thus retained, water is retained with it. This explains the tendency to dropsy observed after large doses of sodium bicarbonate have been taken in the course of diabetes. It is not the bicarbonate that causes the dropsy; the retained chlorid is responsible for it. Under the bicarbonate treatment the output of sodium chlorid in the urine rapidly declines, showing how it is being retained in the body and edema develops in consequence, but as soon as the bicarbonate is suspended, and the elimination of sodium chlorid proceeds as usual, then the dropsy rapidly drains away. The proportion of water in the organism at any given time is thus dependent not only on the amount of sodium chlorid being ingested and on the more or less perfect functioning of the apparatus engaged in the elimination of the chlorids, but it depends also on the ingestion of sodium bicarbonate. Probably the bicarbonate is not the only substance which possesses this property. The chlorid is retained or poured out in a flood at will, just by giving or withholding the bicarbonate. Although it upsets the metabolism to such an extent yet it does not seem to cause any material lesion or permanent modification of the nutrition. As soon as it is suspended the chlorid metabolism proceeds to right itself promptly and effectually. The data reviewed emphasize anew the importance of sodium chlorid in the production of edemas and the connivance of the two substances in producing certain effects.

39. **Cleaning and Scraping the Uterus After Abortion.**—De Bovis discusses the recent contention of Winter that curettage of the uterus after abortion should be reserved for cases in which such complications as hemorrhage render it necessary, but that the physician in ordinary cases should wait until the infection has subsided before he attempts to interfere to clean out the uterus. De Bovis concludes that while there are good arguments on Winter's side the contention should not be pushed too far. The rule should be retained during the primary discussion, to prefer cleansing to curettage and to be chary of intervention, leaving the milder infections alone, in spite of the fact that they sometimes develop an unexpected malignancy. The accumulation of more facts, he hopes, will clear the matter up; if Winter is right, one cannot but admire the boldness which led him to attack so well established a therapeutic dogma.

40. Experimental Research on Tuberculosis of the Kidney.—Pels-Leusden has been experimenting for years to study the mechanism of the development of tuberculosis in one kidney, and here gives the detailed reports of his experiments. He used goats, sheep and dogs and injected the bacilli directly into the artery supplying the organ, without obstructing the flow of blood. Success is possible only when small amounts of very virulent bacilli are used for the purpose. Direct trauma as by a contusion is not necessary for development of the renal tuberculosis, but such a trauma may mobilize bacilli and entail a tuberculous process at some remote point.

41. Chronic Duodenal Ulcer.—Neudörfer reports eight case-histories, all of which sustain his assumption that if a duodenal ulcer does not heal completely under a single systematic course of dieting as for gastric ulcer, an operation is not only justified but imperative. According to the records, operative treatment cured the tendency to duodenal ulcer in from 80 to 90 per cent. of all the cases. The best results seem to be attained with simple gastro-enterostomy, generally supplemented by closing up the pylorus. One of his patients had an ulcer in the stomach with one in the duodenum, and she still has the same symptoms. This may be due to the fact that he did not close up the pylorus in this case or he may have overlooked another ulcer.

42. Operative Treatment of Disturbances in the Large Intestine.—Quervain reports the outcome of an operation eight years ago on a woman with abnormally sagging long transverse colon with mucomembranous inflammation and gallstones. He removed the cecum and ascending colon which put an end to all the symptoms on the part of the intestine. He reviews similar cases on record, the results showing that the colon cannot be resected with a prospect of normal stools; diarrhea or constipation seems to be the rule afterward or they may alternate. His final conclusion is that ileosigmoidostomy is not so good an operation as what he calls ileotransversostomy and in future he will give the preference to the latter.

43. Plastic Surgery.—König has been experimenting with a patch applied outside after suture of a defect in a mucosa-lined cavity. The flap of tissue applied grows into place so solidly that he calls the method "soldering" (Verlöthung). The first time he applied this method was in the reinforcing of a suture after an operation for abdominal hernia; the tissues were so thin and fragile that even the stitch-holes seemed to invite recurrence. He reinforced the suture with a thin flap of periosteum and bone from the tibia, but since then has used the periosteum alone and has now a record of fourteen abdominal and scar hernias which he has safely patched and soldered up in this way. He experimented on dogs to apply this patch method when there were defects in hollow organs and also as a tubular bridge when there was an actual gap in a tubular organ. He gives illustrations of his various experiments and operations in which he thus patched and soldered the bladder and urethra or the rectum. The method is especially adapted for defects after resection of cancers in the rectum. He has found fascia tissue the best for the purpose, obtaining it through a separate incision, not far from the point where it is to be used. The main point is to have the flap in smooth contact all over its surface, so he always sutures the soft parts together above it to press it down into its bed. No tampon should be used. He adds that it is simply amazing to see how the free transplanted flap heals into its new place. Hohmeier reports operations on the same principle on the esophagus, bladder and trachea of dogs, all with promising outcome.

44. Changes in the Fundus of the Eye with Rupture of the Liver.—Tietze has operated in eight cases of rupture of the liver in the last five years. In two of the cases the fundus of the eye showed the same changes to which we are accustomed with albuminuric retinitis. These patients were men of 18 and 30 with severe contusion of the liver region and rupture of the liver requiring suture. In one case the changes in the fundus had subsided by the end of the second day. He queries whether the changes were due to compression or to the anemia.

45. Diagnosis of Injury of the Liver.—Finsterer noticed bradycardia as a striking symptom in two cases of injury of the liver; it seemed directly contrary to what would have been anticipated with the acute anemia. In one case the liver had been ruptured by the kick of a horse and the pulse was only 48. In the other case the liver had been sutured and the pulse was 52. Several writers have mentioned bradycardia with injury of the liver, and ascribe diagnostic importance to it. Finsterer experimented on animals to determine the influence on the pulse of injury of liver and spleen. The results with twenty animals showed that bradycardia is a characteristic symptom of injury of the liver, but that its absence does not exclude injury of this organ. The local pains with injury of the liver may relate to the right shoulder, and the reflex rigidity may extend over the entire abdomen. In two other cases of contusion of the liver region with bradycardia no operation was deemed necessary, but the assumption of injury of the liver was sustained by the development of jaundice and the appearance of bile salts in the urine. In itself, therefore, bradycardia does not necessarily indicate operative treatment. It is important also in prognosis, he thinks; if there is no bradycardia in spite of absorption of bile salts or if, with extreme anemia, the pulse is 70 or 80, the injury requires an operation at once, the prognosis being graver than when the pulse is abnormally slow.

46. Venous Anastomosis in Treatment of Varices.—Hesse and Schaack describe experiments on the cadaver and on animals which show the feasibility of implanting the saphenous vein in the femoral vein, 10 cm. below its normal site, in the treatment of varices. The arrangement of the valves and the anatomic and physiologic conditions tend to restore normal conditions in the venous circulation. Delbet published in 1906 eight cases and has reported sixteen since in which he has applied this method, but since then it does not seem to have been applied, possibly owing to the little notice paid Delbet's communication and to the tedious technic. Hesse and Schaack here report the successful application of the method in twenty-six cases. They give the details of the first twenty-three cases and commend the operations as restoring physiologic conditions. If the fine results attained to date prove permanent the method has a future. In their cases all the varicose ulcers had healed, all the edema had subsided and the patients were free from all subjective disturbances. Only one case was a failure. The wound healed but by the end of a week deep infection was evident and the patient succumbed the twenty-sixth day to suppurative thrombophlebitis of the two veins, with superposed pneumonia.

51. **Correction of Pendulous Abdomen.**—Jolly reports two cases in which he has relieved patients from pendulous belly by resecting the pendant portion. A curving incison was made near the umbilicus from groin to groin and then another, with a sharper curve, is made below, both incisions starting at the same point on each side and the two outlining a crescent. The pendant mass of abdominal skin and fat thus circumscribed is cut out and the upper and lower incisions are sutured together. He gives an illustrated report of his first case; the lips of the wound left by resection of all the tissues down to the fascia were held together with forty Michel clips. One of his patients had long had painful disturbances from the pendulous belly as she strove to keep it under control with corsets. Jolly has been able to find in the literature only two communications on operative correction of pendulous belly, one from Demars, a French surgeon, and one from Schulz, a Russian, who reports three cases. The linear scar left from the transverse crescent incisions is scarcely perceptible; there is little, if any, bleeding at the operation, and Jolly regards it as simple and entirely harmless, possibly more so than strenuous measures sometimes undertaken by women to reduce their flesh to get rid of their sagging belly and which rarely accomplish their purpose, while this is promptly realized by the simple operation described with illustrations.

52. **Differentiation of Benign and Malignant Hour-Glass Stomach.**—Kretschmer gives some illustrations of the findings with radiography of hour-glass stomachs which demonstrate, he thinks, that it is safe to assume malignant disease when the hour-glass constriction is horizontal and vertical, the radiograph showing an extensive horizontal and vertical defect in the outline of the stomach. With non-malignant anomaly the constriction is more or less horizontal. With the non-malignant hour-glass stomach the upper sac empties itself into the lower, while with malignant disease both halves of the stomach seem to empty themselves regularly together, without the lower sac filling up first.

54. **Influence of Calcium Salts on Production of Effusions.**—Levy's experimental research failed to demonstrate that calcium chlorid has any inhibiting action on the production of effusions.

57. **Operative Treatment of Pulmonary Embolism.**—Ritzmann has found by numerous experiments on the cadaver that Trendelenburg's operation to expose the pulmonary artery to remove an embolus is entirely practicable from the anatomic standpoint although none of the five patients thus operated on was permanently cured. Ritzmann has been studying the fifty-five cases of an embolus in the pulmonary artery which he has encountered during the last 6,000 necropsies. The embolism followed operations on the trunk or legs in six of the thirty-five cases of which the details are known: it followed injuries of the legs in three others, varicose disturbances in the legs in seven, anemia and cachexia in eight, and it occurred with a heart defect in three. In only six cases was the diagnosis of pulmonary embolism made during life, and in these cases the embolism proved rapidly fatal. In all the others there was an interval of from half an hour to forty-eight hours between the onset of the symptoms of embolism and the fatal termination. An interval of from three to six hours was the rule, and it is probable that the embolus gradually increased in size or that the embolism occurred in waves. This is evidenced by the transient improvement under camphor, and the discovery in the smaller arteries at necropsy of minute emboli evidently older than the big one that proved fatal. The data show thus, he remarks, that the diagnosed embolism proved too rapidly fatal for any operative intervention, and that in the cases with a sufficiently long interval for operative interference to have been successful, the nature of the disturbances had not been recognized. The embolus was generally located in the main trunk of the artery or one of its chief branches, and from the pathologic-anatomic standpoint might easily have been removed. The great difficulty therefore in the way of successful operative treatment of pulmonary embolism is the failure to recognize it in time. Bloody sputum at the beginning of the disturbances is an almost constant symptom. The mechanical factor should be considered in diagnosis as the embolism occurred almost invariably after sitting up in bed, getting up, changing the dressings, or after the agitation stage of general anesthesia. An instance has been reported recently in which the embolism followed application of a constricting band to induce hyperemia. The condition of the heart and lungs when the embolism occurs is a decisive factor in the outcome, as also conditions favoring thrombosis. On suspicion of pulmonary embolism a surgeon who has mastered Trendelenburg's technic need not hesitate to apply it to save an otherwise doomed patient.

62. **Consanguineous Anomalies of Development.**—The authors report a peculiar anomaly of development of the ectoderm which was transmitted only to the male offspring through the female; none of the developmental errors were at any time noticed in the females, nor were all the males affected. The original progenitor of the patients whose cases are reported was twice married. By her first husband she had four children, only one of whom was affected by the anomaly to be described. One of the well children gave birth to fifteen boys, four of whom showed the anomaly. By her second husband the original progenitor gave birth to eleven children, two of the boys showing the anomaly. One of the well children gave birth to one child, a boy, who also showed the anomaly. The congenital maldevelopment consists in a hypotrichosis, a saddle nose, misshapen ears, absence of teeth, in part or entire, with misformation. The fingernails were normal. The growth of hair on the head, face and body was exceedingly sparse. The eyebrows were absent, while the eyelashes were well developed. The beard was very sparse and only a few hairs were present on the chest and in the axillæ. The skin was normal [illegible] or but appeared to be rather loose and was very dry. T[illegible]italia were well developed. The ears were of the type kn[illegible] as satyr ear. There were no evidences of syphilis; th[illegible] Wassermann reaction was negative. When teeth were present they were flask-shaped. The jaws were atrophic and did not contain teeth germs. Although the patients could not be called imbeciles their mental development was noticeably deficient. None of them perspired.

Centralblatt für die Grenzgebiete der Medizin und Chirurgie, Jena

June 24, XIV, No. 9, pp. 321-368

67 *Tuberculosis of the Kidney. (Ueber Nierentuberkulose.) K. Frank.
68 Nodular Rheumatism. O. Willner.

67. **Tuberculosis of the Kidney.**—Frank reviews, with comment, 527 articles bearing on renal tuberculosis. The mortality in 1,331 nephrectomies for tuberculosis has been 9.3 per cent. in the years since 1900 in the experience of thirty-five surgeons, including Kelly's thirty-five cases (1904), with 14.2 per cent. mortality, Rovsing's 106 with 5.7 per cent. mortality (1909), and Albarran's 188 cases with 3.3 per cent. mortality (1908). The mortality has grown constantly less with the progress in diagnosis and technic; Pousson, for instance, reported in 1902 a mortality of 33.7 per cent. in 335 operations, while it was only 11.6 per cent. in the forty-three operations reported in 1908. In the first half of the last decade the mortality in 137 operations was 18.2 per cent., while it was only 8.2 per cent. in the 1,194 operations 1905-1910. The ultimate outcome of many of the cases is also recorded. The results seem to show that there is little danger of ascending non-tuberculous pyelonephritis from the bladder after removal of one kidney. It occurred only once in Israel's experience. Heal-

ing of the bladder lesions had better be promoted by local measures after the nephrectomy. Rovsing reported spontaneous cure of the tuberculous lesion in the bladder in fourteen cases; in twenty-five others there was propagation of minute foci or the lesions persisted unmodified. He advises after waiting a little to inject, after the bladder has been well rinsed out, 50 c.c. of a fresh and warm 6 per cent. solution of phenol, allowing it to be retained for two or three minutes in the bladder and then evacuated, repeating this until the solution comes away rather clear. He repeats this at longer and longer intervals; the course requires six or eight weeks. The measure is painful and may require injection into the bladder of some sedative. An opium or morphin suppository is given afterward. Occasionally signs of phenol poisoning were observed, black urine, nausea and vomiting, but all transient and never serious. The treatment proved successful in a number of apparently hopeless cases, and Lichtenstern, Bonamone and Lower have also reported good results with it, but Rafin and Stossmann advise against local measures as useless and liable to do harm. Hunnêr found it necessary to make an opening from the bladder into the vagina to relieve the disturbances after nephrectomy in one case; sitz baths were often found useful also.

Deutsche medizinische Wochenschrift, Berlin

75 Veratrum Viride in Eclampsia Gravidarum. E. G. Zinke.
76 Recent Methods of Diagnosticating Malignant Growths. H. Hirschfeld.

70. **Effect of Arsenic in Chlorosis.**—The effect of iron and arsenic and of both combined in chlorosis was studied by Seiler in thirty-three cases. In thirteen cases arsenic alone, in twelve cases iron only, and in eight cases iron and arsenic in combination were given. The arsenic was given in the form of arsenious acid, 0.005 to 0.01 gm. in pill form, or injected subcutaneously. The results were *nil.* While the hemoglobin percentage was a little higher in some cases after two or three weeks' treatment, the number of red cells was on the average reduced. Therefore it is concluded by the author that chlorosis should not be treated with arsenic alone. The patients who received the iron treatment were given a modified Blaud's pill for four weeks. The results on the whole were rather satisfactory. The hemoglobin percentage was markedly increased, almost doubled, whereas the number of erythrocytes was increased to normal. When both iron and arsenic were administered the result was a most astonishing one. For instance, if at the beginning of the treatment the hemoglobin was 37 per cent. and the erythrocytes, 3,000,000, at the termination of the treatment the findings were hemoglobin, 96 per cent.; erythrocytes, 5,000,000. It is quite evident, therefore, that the proper treatment of chlorosis is to use a combination of iron and arsenic.

73. **Phenolphthalein Test for Occult Blood in Feces.**—Goldschmidt confirms Boas' findings with reference to the value of the phenolphthalein test for detecting occult blood in the feces. He believes that this is the best test for the general practitioner because it is performed easily and quickly and with almost no apparatus.

74. **Surgery of Paralytic Deformities.**—Böcker advocates the transplantation of tendons for the correction of all paralytic deformites of the feet. However, this should not be undertaken until thorough stretching of the tendons has, beyond question, failed to produce any result. If electricity fails to produce any reaction in the muscles involved a central paralysis is, of course, present and then, depending on the condition of the muscle fibers, a corrective operation should be undertaken. The author reports several illustrative cases. In one of these there was complete paralysis of the peronei, tibialis anticus and extensor digitorum communis. He transplanted the flexor hallucis longus to the peronei and the extensor hallucis longus navicular bone. The tibialis anticus was transplanted to the cuboid bone. The result was satisfactory.

78. **Esophagoplasty.**—The unsuccessful outcome of a case of esophageal carcinoma in which the patient was operated on according to the method of Roux, led Lexer to modify the procedure by substituting for the piece of intestine a skin flap. Two patients operated on according to this method in 1903 and 1904 got along very nicely, the wounds healed kindly without fistula formation and function was perfect. Only the neck portion of the esophagus is formed of skin; for the remaining portion the intestine is used according to the Roux method. In November, 1907, Lexer extended this procedure so that the entire esophagus was rebuilt from skin. The incision was begun 2 fingerbreadths above the sternal notch extending 6 centimeters to the left of the median line. It was then continued downward 3 fingerbreadths below the margin of the ribs, then extending inward to the median line. This huge skin flap was then separated from the underlying tissues and rolled up to the right so as to form a tube with a lumen large enough to admit the entire finger, the epidermis being on the inside. The skin of the chest was then loosened by undermining so that it could be drawn together covering the defect made by the flap and thus burying the skin tube completely. About a month afterward the lower mouth of this tube was anastomosed with the stomach and when healing had occurred there was a continuous patulous duct from the neck to the stomach. Lexer had contemplated making an anastomosis between the pharynx and esophagus but the patient succumbed to gangrene of the lungs incident to a recurrence of the carcinoma about two months after the original operation. Lexer concludes from this operation that the principle of the operation is correct. In another case he adopted the combined procedure using a loop of jejunum to replace the esophagus as high as the mammæ and above that making a skin tube. The result was a most gratifying one. The patient is able to swallow food although fluids must be taken at the same time in order to wash down large boluses of food. At first the patient complained of considerable itching in the skin portion of the esophagus but this soon subsided. Eight months have elapsed since the final operation and the patient is enjoying the best of health.

82. **Anesthesia of Brachial Plexus.**—Hirschel reports two cases in which he operated successfully on the elbow and ulna for the removal of fractured bones, and in a third case for tuberculous osteomyelitis, all under local anesthesia of the brachial plexus. The anesthetic was injected directly into the plexus.

85. **Arthritis Caused by Measles.**—A 6-months-old infant developed a typical attack of measles which ran the regular course and terminated in complete recovery. About five days afterward when no further effects of the measles were apparent, there developed a swelling and redness of the right large toe and dorsum of the foot. A similar condition developed

in the left foot and the right wrist and right elbow. All of the joints so involved were intensely painful, subjectively as well as objectively. The right hip and right knee next became slightly painful. The heart, lungs and other organs were apparently normal. There was very little elevation of temperature and inside of *twenty-four hours the pains began to* subside and the swelling became less. There was a slight leukocytosis and little poikylocytosis. When the patient was seen again, a week later, recovery was complete. Feibelmann believes that this was a typical rheumatoid condition caused by the measles. The case is interesting not only because of the arthritis following measles, but also because of the age of the patient.

87. **Acoustics of Heart Tones.**—Lillienstein calls attention to the fact that it is of the greatest importance to be able to differentiate valvular and pericardial adventitious sounds. This is hardly possible by means of the instruments and apparatus hitherto in use. Lillienstein has devised what he calls a cardiophone or a microphone stethoscope which makes accurate diagnosis possible. The heart tones are very easily appreciated by means of this instrument and any deficiency from the normal is quickly detected. Valvular tones may be differentiated from pericardial friction or other sounds, and the various sounds heard during respiration. both in well and diseased lungs, are easily heard. The instrument is easily portable. The illustration shows the method of construction of the apparatus.

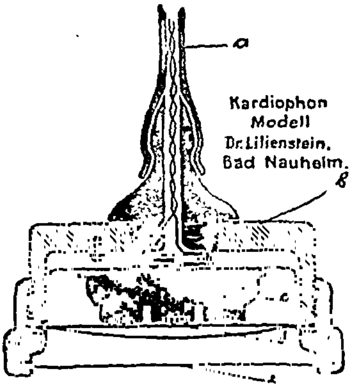

Figure showing Lillienstein's cardiophone; a, electric wiring; b. enclosed capsule; c. carbon; d, carbon membrane; e, hard rubber or celluloid membrane.

88. **Inversion of the Appendix Vermiformis.**—Langemak reports the case of a boy 4 years old who complained of pain in his right hip. Temperature was normal; there was no vomiting; no abdominal tenderness; no pain on pressure. Under the right Poupart's ligament an intra-abdominal mass was palpable, slightly tender on pressure and almost fixed. There was slight abdominal rigidity. Below Poupart's ligament was a fluctuating mass which was assumed to be an abscessed gland. In the meantime the temperature rose to 40.7 C.; pulse. 144. A diagnosis of epityphlitis was made. At the operation it was found that the appendix had become entirely inverted into the cecum. By means of gentle massage it was possible to reduce the invagination. Only fifteen similar cases have been reported in the literature.

89. **Skin Pigmentation in Addison's Disease.**—It is believed by Stümpke that the excessive pigmentation of the skin in Addison's disease is not the result of excessive pigment formation in the adrenals but that this occurs in the skin itself as the result of the action of the secretion of the adrenals which reaches the skin through the circulation.

97 *Unsuspected Cancer as Cause of Hiccup. (Beitrag zum Kapitel "Singultus.") J. H. Greeff.

97. **Hiccup Due to Unsuspected Cancer.**—In Greeff's case the singultus persisted unmodified by all measures until the death of the patient, six months after the hiccup had first commenced to torment him. He was a man of 76, and the singultus developed a few weeks after recovery from pneumonia with pleurisy. The singultus recurred at intervals of only a few minutes, seldom more than a quarter of an hour, and there was occasionally a shrill intonation at the end of the hiccup showing the violence of the diaphragm spasm. Necropsy revealed a small tumor in the hilus of one lung, evidently a primary malignant growth, and probably responsible for the singultus by compression of the phrenic nerve directly or indirectly, although no positive evidence of this could be discovered.

SOME COMMENTS AND SUGGESTIONS CONCERNING THE WELFARE OF THE SECTION ON OPHTHALMOLOGY*

ALBERT E. BULSON, JR., B.S., M.D.
FORT WAYNE, IND.

In assuming the position of Chairman of this Section, I desire to express my thanks for the honor that has been conferred on me, and to assure you of my keen appreciation of the compliment you have paid me in selecting me to preside over your deliberations.

To be Chairman of the Section on Ophthalmology is an honor of which one may be proud. The Section was the first one of the Association, having been organized in 1879 with less than 100 members. It has steadily grown in size and importance until it has at present over 1,200 members, who, according to the rule adopted by the Association office, are active members as a result of registration in the Section during the past five years; and if we include as members all those who hold membership in the Association and who have registered in the Section during the last ten years, the membership is over 1,700. This membership includes practically all of the prominent and progressive ophthalmologists of this country, and from the amount and character of work that has been done and is being done, the Section is entitled to rank as one of the foremost ophthalmologic societies of the world.

But the organization does not exist which is so good that it cannot be made better, and in keeping with the spirit of the Constitution and By-Laws of the Association, which prescribe the character of the Chairman's address, I shall briefly discuss some features connected with the conduct of the Section, and offer a few suggestions and some recommendations which, if adopted, in my judgment, will add to the future reputation and usefulness of the Section.

The plan of sending the printed papers to the active members of the Section in advance of the annual session at which such papers are to be presented and discussed has now been in operation six years and has proved an unqualified success. Not only has it led to the preparation of better papers, but it has given the members an opportunity to read carefully and to study thoroughly the matter to be presented by the various essayists, and has stimulated more and better discussion at the meetings. It has also given opportunity for the careful preparation of discussions in advance and eliminated in a large measure the rambling and ofttimes inapplicable discussion heard at meetings where the matter contained in papers is first presented when the authors read from their manuscripts. The belief among some that the discussion of papers that have been given to the members prior to the sessions would lead to discussions devoid of originality has not been borne out by the results, for never in the history of the Section have the discussions been as comprehensive and yet original as they have been since the adoption of the plan of distributing the papers in advance in the form of our presessional volume. In expressing a desire for a continuation of the plan, I wish to make a plea for an earlier publication of the presessional volume with a view to placing the papers in the hands of the members of the Section at least 30 days before the annual session at which the papers are to be presented. This is entirely possible if the manuscripts are in the Secretary's office not later than March 15, and any member who desires a place on the program can have his manuscript ready at the appointed time if he will start earlier with his work on it. Probably a majority of our essayists prepare papers under pressure, and are apt to procrastinate. To complete a paper a week or ten days earlier is not a matter of much concern, if it is known months in advance that the completed manuscript must be in the hands of the Secretary of the Section at a certain time.

I also desire to make a plea for more written discussions or discussions from well arranged notes on the part of those who take part in our meetings. Even the best of our members, though there are many who are concise and forceful speakers, are apt to be guilty occasionally of rambling, disconnected and irrelevant discussions if the same are given wholly extemporaneously. This has been forcibly illustrated by a comparison of the stenographer's report of extemporaneous discussions with the same after revision and extended alteration at the hands of those who gave the discussions.

The plan of appointing members to open the discussion of papers should be continued, but the appointments should be made earlier and acceptances received before the final program goes to press, and each member accepting such an appointment should consider that he is as much under obligation as the essayist and his formal discussion should be prepared with such thoroughness and comprehensiveness as the subject demands.

Notwithstanding the action of the Executive Committee concerning the rule to be followed by the officers in arranging the program for this session, I desire to express my emphatic objection to a lengthy program necessitating long hours and an added meeting on Friday morning. I know that I voice the sentiment of a large number of the prominent and active members of this Section when I say that the best interests of the Section are subserved by having a few papers well and thoroughly discussed and within such time that the members are not completely tired out or unnecessarily bored before the session closes. To continue some of our morning meetings until 12:30, and some of our afternoon meetings until 5:30 or 6 o'clock, and even then crowd out much discussion in order to complete a long program, is not conducive to the best efforts and results, and it tires the members too much, to say nothing of the officers who are in duty bound to remain until the adjournment. If the morning meeting is called at 9 o'clock, or better still at 9:30, and adjourns not later than 12, and the afternoon meeting is called promptly at 2, and adjourns at 4:30 or not later than 5, the members will have had all they can stand in the way of a scientific treat, provided the program is followed as closely as it is by the more active and interested members. Not more than five good papers can be presented and properly and thoroughly discussed within the time allowed for one meeting, and five meetings, ending with the afternoon meeting of Thursday, are sufficient to satisfy fully 90 per cent. of the members.

---

* Chairman's Address before the Section on Ophthalmology at the Sixty-Second Annual Session of the American Medical Association, held at Los Angeles, June, 1911.

No paper on the program should be presented out of its order, as it is unfair to the other essayists and to the members of this and other sections generally to have the order on the official program changed, with its possible disappointment to many who have arranged attendance in order to hear certain papers. Furthermore, we should follow the very stringent rule adopted by the Section several years ago, to the effect that any member who accepts a place on the program and defaults shall not be privileged to present a paper before the Section for a period of three years, except at the discretion of the officers and Executive Committee in accepting an excuse. It is already the rule that a paper on the program not actually presented and defended by the essayist shall not be published in the transactions of the Section except by unanimous vote of the Section, and I wish to make the recommendation that we eliminate that portion of the rule which provides for any publication of the paper on the recommendation of the Section until after the paper has been actually presented before the Section. In my judgment it establishes a bad precedent to refer papers by title for publication in either the Transactions of the Section or The Journal of the American Medical Association.

If, through absence of any of the essayists, or as a result of limited discussion of papers, the program of any meeting is shortened, a subject, previously selected by the officers for such a contingency, may be offered for discussion. Undoubtedly such a feature would prove an interesting and profitable innovation. For instance, if at this meeting the program should be completed at too early an hour for adjournment, we might discuss the subject of the effect of salvarsan, or what is popularly known as "606," on the eye. Comparatively little on the subject has been written in this country, and you will note that our program has no reference to it. Other equally practical subjects might be suggested for a kind of "round table" discussion, and such a feature, it seems to me would prove very acceptable. I am told that the British Medical Association regularly gives up a part of the time of the regular program to such a feature and that it has proved a decided success.

Another portion of the surplus time, if there should be any, could be given to that part of our program which of late years has been set aside for demonstrations or the presentation of new instruments or appliances. This feature, it seems to me, could profitably take more time than we have heretofore been accustomed to give it.

Therefore, in consideration of the propriety of having fewer papers, of giving opportunity for more and better discussions, and of affording an opportunity for the introduction of other features, I desire to make the following specific recommendations: First, that the Section adopt a rule to the effect that the entire program shall not consist of more than twenty-five papers, exclusive of addresses; second, that at the discretion of the officers, and with the approval of the Section, for any unfilled number on the regular program there may be substituted a general discussion on some subject selected by the officers or proposed by some member of the Section; third, that the presentation and discussion of papers shall end with the meeting of Thursday afternoon; fourth, that if the officers and Executive Committee arrange any program for Friday the same shall be in the nature of clinical or social features; and, fifth, that no paper shall be approved for publication in the Transactions of the Section or in The Journal of the American Medical Association unless such paper has been actually presented by the essayist before the Section.

This leads me to a discussion of the merits of papers which should be accepted for the program. In such a large Section it is natural to suppose that a large number of papers will be offered for each annual program, and such is the case. For each of two eastern sessions within recent years over 140 papers were offered. The selection of a program from this large number of papers is a task for the officers and Executive Committee, and one that is not always devoid of embarrassment, owing to the difficulty of making selections from an abundance of good material. However, in the selection of papers for the programs of this Section, the utmost fairness has prevailed, and as Secretary of this Section for a period of seven years and being familiar with the action of officers and executive committees during that time, I am free to say that on every occasion an effort has been put forth not only to select papers of originality and unquestioned merit for each program, but to exhibit fairness in the distribution of favors by selecting papers with due regard to geographic location of essayists as well as age of the members. While it has been the unwritten rule, which should be continued, that mediocre maiden efforts should find no place on our programs, the young men who have in one way or another demonstrated their ability have been encouraged to offer contributions, and have met with the most cordial treatment at the hands of executive committees. Let us not forget that the ophthalmology of the future will be written by the young men of to-day, and that many of these men, because of the superior advantages and training they have in this day and the facilities that are offered for original work, are developing new truths which it should be to our pleasure as well as to our profit to hear or see demonstrated. The older and more noted men in ophthalmology do not possess all the knowledge pertaining to our specialty, and for that reason I am in favor of giving the young man of training, if not experience, a chance to be heard.

Our programs should be practical as well as scientific, and to that end demonstrations and the exhibition of charts, photographs, specimens and new instruments and appliances, should be encouraged. Whenever the Association meets where it is possible, the giving of clinics, both medical and operative, serve a useful purpose for the presentation of rare and interesting cases or the demonstration of new forms of operation or treatment. Such a feature could with propriety form the only program for Friday. This was the plan pursued at St. Louis last year, and it proved a great success, and it was an attractive feature which many members have expressed a desire to have repeated.

A criticism that I would offer concerning the work of the Section is the lack of purely original work. Too often our programs are made up entirely of papers that are simply a review of the literature on various subjects or represent the authors' clinical experiences, or perhaps simply represent the report of what are considered interesting and rare cases. I do not wish to belittle the value of reports concerning clinical findings with appropriate deductions, for I feel that the clinical side of our work ought to receive a good share of attention, but the matter of pure investigation certainly does not receive the consideration that it deserves, and it was a recognition of this fact that in a large measure led to the establishment of the Knapp Testimonial Fund and the offering of a medal for original research work.

In this connection I wish to endorse heartily the recommendations of one of my distinguished predecessors, Dr. W. H. Wilder of Chicago, to secure collective investigation by the appointment of committees to study definite subjects of scientific and practical interest to us as ophthalmologists, and I wish to urge the committees appointed as a result of the recommendation, to continue their investigations and to make reports before this Section at stated intervals.

The recommendation of another former Chairman, Dr. A. A. Hubbell of Buffalo, that the Section consider the subject of the proper qualifications of the ophthalmologist and endeavor to secure a recognized standard for the practice of ophthalmology as a specialty, it seems to me, is worthy of more consideration than was given it at the time the recommendation was made. Concerning this subject I am in hearty accord with Dr. Hubbell when he says:

> It is unfortunate, however, that no qualifications for practice have heretofore been required of the ophthalmologist other than those of the general practitioner, but his sense of justice, his pride and his taste for the subject have stimulated him, in a large proportion of cases, to prepare himself creditably for his work. The absence of these and the presence of a dominant spirit of commercialism, have, on the other hand, caused him to make too much haste to begin his practice, limiting his study to an undergraduate course, with perhaps a few weeks in postgraduate work. He neglects taking the necessary time for study, disregards important subjects, fails to acquire personal clinical experience—in short, he is an unprepared, unqualified specialist—an ophthalmolgist only in part. Ophthalmologists are rapidly increasing in number, and the unqualified ones are also becoming correspondingly too numerous. The ophthalmologist, of course, like other specialists, should possess knowledge of his subject much more extended and complete than that of the general practitioner, and by wider observation and larger experience he should be far more proficient and skilful. Indeed, he should be an expert in this department of medicine. When, therefore, one lacks the necessary qualifications for such a position, he should not be allowed to assume it, both because of the harm he may do to patients and because of the injustice he inflicts on the rights of his neighbor ophthalmologist, who has qualified at much sacrifice of time, energy and money.
>
> In order that protection may be secured against unqualified ophthalmologists, I suggest that the course and subjects of study which the ophthalmologist shall pursue be regulated by law, and that a special board of examiners shall be appointed to act alone, or in association with general boards as now constituted, to determine his fitness, and, if found qualified, to authorize a license to practice to be issued to him.

In an able paper by Dr. Edward Jackson of Denver to be presented before this Section at this session, the subject of the proper qualifications of the ophthalmologist is discussed in the closing paragraphs from which I abstract the following:

> As matters stand now, the graduate, after a scanty introduction to ophthalmology in the medical school, is permitted to pick up ophthalmic knowledge and skill here and there: from desultory reading, by study of chance cases, in the unsystematized clinics of postgraduate schools, from the courses of self-constituted teachers, and by a partial return to the apprentice system through assistantship in the eye clinic or private office.
>
> This has made ophthalmologists of apt students, sufficiently conscientious to persist in the effort to obtain knowledge under difficulties. But it has also created a large number of fakers within the profession—men who pose as specialists before colleagues slightly less informed than themselves, and before the still more ignorant public. This system, which is a lack of system, has not met the legitimate needs of the profession, or the best requirements of the public. The feeling that, although a physician's license to practice gives the privilege of ophthalmic practice, it does not guarantee any fitness for such practice, has led the public to be ready to look for ophthalmic advice outside the profession as well as in it.
>
> The establishment of the degree of doctor of ophthalmology, and of the course leading to that degree, in the University of Oxford points to a practical way of meeting the need of the profession and the public for some authentic evidence of fitness to practice ophthalmology. The offering of such a degree, based on requirements of graduation in medicine and evidence of special acquaintance with ophthalmic science and art, by a few of our better American universities would sweep away the false conditions, the lie in medical education, out of which the optometry question has grown. There can be no better time than to-day, and no better place than the Section on Ophthalmology of the American Medical Association, for starting a demand on the part of the medical profession for the adequate teaching of ophthalmology in all well-equipped, efficient schools of medicine.

My apology for appropriating from the presessional volume these remarks of Dr. Jackson, is that the presentation of the subject in the manner indicated is entirely in accord with the views I had in mind in entering on a discussion of the subject, and I desire to take this occasion not only to endorse all that Dr. Jackson says but to suggest that this Section should recommend some standard of qualifications which shall be recognized as entitling a physician to the title of ophthalmologist.

The question of having a noted foreigner as a guest of honor of the Section is one that has met with varying degrees of approval from active members of this Section. We have been favored by having as our guests, and hearing addresses from, such distinguished men as Haab, Hirschberg, Ramsey, Hess, Collins and Parsons. They have added to the richness of our literature, and their presence has been an inspiration as well as a social feature which has given pleasure and profit to those who were fortunate enough to hear and see them. The advisability of having a guest of honor every session may be questioned, as also the effort to secure a guest for any particular session at the expense of numerous invitations which bring regrets. At the request of the Chairman, and with the approval of the Executive Committee, an invitation in the name of the Section was extended consecutively in one year to four noted ophthalmologists in Europe, only to bring regrets in each instance. The following year I heard it intimated by some of our European confrères that an invitation to be the guest of the Section on Ophthalmology was not difficult to obtain, inasmuch as invitations were distributed freely. To be the guest of this Section, representing practically all of the prominent and progressive ophthalmologists of the United States, and to receive honorary membership in the American Medical Association as one of the rewards, should not be an honor to be looked on lightly, and our invitations should not be so numerous or extended so promiscuously as to encourage the belief that the honor is a common one. Our efforts should not be to secure a guest at any cost, but to secure a guest who is entitled, through his standing as an ophthalmologist, to distinctive honor by the American ophthalmologists, and who in turn will, by his presence and the part he takes in our proceedings, stamp his visit as an event of scientific and social importance in the history of the Section. Furthermore, an invitation to be the guest of this Section should not be extended unless we are reasonably certain that the one who is to be invited will accept the invitation with the intention of fulfilling the obligation. The expense of entertainment of the guest while attending the session of the A. M. A. should be met by the Section and not by the officers and a few prominent members who are always ready to contribute in order to show our guests proper hospitality. Once in two or three years is often enough for us to have a guest of the Section as a feature of any session.

The Knapp Testimonial Fund, proposed and inaugurated by my immediate predecessor, Dr. W. C. Posey of Philadelphia, and myself, is a feature which it seems to me is pregnant with great possibilities in advancing the welfare of the Section. At the St. Louis session the purposes of the fund and the plans for its use were outlined and the same were approved unanimously by the Section. As is now well known, the fund is raised by voluntary pledges of varying sums from those members of the Section who are sufficiently interested to contribute a definite amount each year. Quite a large number of the members have become contributors on the understanding that they are to give a definite sum each year, but I regret to say that all those who ought to contribute to the fund have not done so, though probably this is due to an oversight rather than a lack of desire to aid an exceptionally worthy cause. I desire to urge every member of the Section to give something, even though it is no more than one dollar per year, and the fund will not grow too large for the purposes under consideration. In fact, I am distinctly in favor of efforts to secure, if possible, sufficient funds to established a principal, the income from which will be enough to enable us to carry out the plans already adopted.

The Knapp medal of the Section on Ophthalmology.

It was proposed that the Knapp fund should be maintained and used essentially for the purpose of stimulating research work and encouraging the highest type of scientific contributions in the field of ophthalmology. To this end it was decided to procure a medal, to be known as the Knapp Medal of the Section on Ophthalmology, and offer the same to invited as well as uninvited contributors to the Section on Ophthalmology for original work in ophthalmology, or for some contribution of such a highly meritorious character in the field of ophthalmology as will warrant the granting of a medal as a special recognition. It was also proposed to use a portion of the fund for the granting of a money prize to be used in carrying on any original investigations at the instance of the Section. It was further proposed that a portion of the fund should be used to meet the expenses of the Scientific Exhibit and various practical demonstrations. Provision was also made for minor expenses not already provided for by the Association in promoting the welfare of the Section.

The plan as outlined was approved by the Section, and the officers and Executive Committee were made a committee to carry out the purposes as outlined. In conformity with the action of the Section, I have the pleasure of exhibiting a design for a medal to be known as the Knapp Medal of the Section on Ophthalmology, to be offered annually for purely original work in ophthalmology, which shall be presented before this Section and be deemed by a committee, appointed for the purpose, worthy of special recognition. It is proposed that the medal shall be made of gold, and that on the reverse side shall be engraved the name of the recipient of the medal, the date when the medal was presented, and for what it was granted. It is also proposed that but one such medal be offered, that one contribution only shall receive a medal in any given year, and that the medal be not granted in any year unless the contribution offered in competition for the medal shall be of such a distinctly meritorious character as to meet with the approbation of the committee appointed to pass on the merits of such contribution. It is also proposed that the sum of $100 be set aside annually to be used, on the recommendation of the Section and at the discretion of the committee, to further research work carried on by order of or under the direction of the Section, but that no second appropriation be made until the first one shall have been exhausted.

In furthering the purposes as outlined, I desire to recommend that the Secretary of the Section, when sending out his annual announcements, shall include a printed circular calling attention to the medal and prize, and the conditions under which they are bestowed.

Since our last session death has removed from our ranks a large number of prominent members, among whom I may mention: Drs. A. W. Calhoun of Atlanta, A. R. Baker of Cleveland, and Leartus Connor of Detroit, all ex-chairmen of the Section. Others who were prominent and active members of the Section and who have died within the past year are: Drs. Charles Stedman Bull of New York, Henry Gradle of Chicago, Charles A. Oliver of Philadelphia, C. J. Kipp of Newark, N. J., and Herman Knapp of New York. To each and all of these deceased members the Section owes much of its success, for they labored to bring the Section to its present standing as the foremost ophthalmologic organization in this country.

In preparing the program for this year the officers of the Section have met with some disappointment in having withdrawals at the last minute and a few of the essayists whose papers appear in the presessional volume have, in consequence of sickness or other equally valid excuse, been prevented from being present. There are, however, enough papers to engage our attention for the time at our disposal, and I am satisfied that the discussion will prove interesting and profitable to all. It is with pleasure that I welcome you, old members as well as new, in this garden city of the Pacific Coast where the most cordial and generous hospitality has been extended to us, and I bid you take up the Section work that is before you with an earnestness and thoughtfulness which presages a profitable and pleasant session.

219 West Wayne Street.

AN EPIDEMIC OF CHANCRES OF THE LIP FROM KISSING

JAY F. SCHAMBERG, M.D.
PHILADELPHIA

The following epidemic is a distressing instance of the innocent transmission of syphilis.

A coterie of young men and women, varying in age from 16 to 22 years, gave a minstrel performance as a benefit. Following this, a party, and later a banquet, were given at which juvenile kissing games were indulged in. One of the participants, a young man of 22, had a sore on his lip, the nature of which he avers he did not know. Six young women kissed by him developed chancres of the lip. A young man present at the affair likewise developed a chancre of the lip apparently from the virus deposited on the lips of one of the young women, for he did not come into contact with the original source. In addition, a young woman kissed by the offender at a third social function likewise developed an initial sclerosis, making in all eight labial chancres from the one source.

The matter was called to the attention of the Department of Health of Philadelphia by a physician under whose care three of the patients came. Dr. Joseph Neff, the director of the department, asked me to investigate the outbreak. Further study brought to light knowledge of the remaining cases.

The original offender was apprehended by a detective and brought to the health department quarters in City Hall. I examined the young man and secured the following history: The patient first noticed a sore on the left side of the lower lip about Feb. 12, 1911; March 3, he consulted a physician who, according to the statement of the patient, did not inform him of the contagious nature of the lesion. The physician on being interrogated declares that he advised the young man to take all precautions; there is, therefore, a question of veracity between the patient and his physician.

March 4, the patient attended an evening party at which kissing games were played and at which most of the young women were infected. March 18, he attended a banquet, after which similar osculatory games were indulged in.

At the time of my examination, about June 20, he presented the remains of a chancre of the lower lip, pronounced tonsillar ulceration with mucous patches, and a maculopapular eruption over the trunk.

There is no law in this state specifically giving the right to the health authorities to deprive a syphilitic of his liberty during his period of infectivity, but there is an old law of almost a century ago empowering the board of health to quarantine a person who is known to be spreading a contagious disease. This patient had so carelessly spread a serious disease that the authorities felt called on to prevent further infection. With the patient's consent he was taken to the municipal hospital and an intravenous injection of salvarsan given. Had the patient refused, he would have been quarantined.

The data concerning the unfortunate patients who innocently contracted syphilis are as follows:

Case 1.—A young woman, aged 20, developed a sore on her lip in the early part of April and on the fifteenth of that month consulted a physician, who found an indurated lesion both on the upper and lower lip and marked adenopathy. The nature of the lesion was recognized by the physician and the patient was immediately placed on treatment. She later developed tonsillar ulceration, mucous patches and some eruption on the trunk. When I examined her later, she had tonsillar ulceration and the remains of the labial chancre. July 8 the Wassermann was strongly positive. She was given an intravenous injection of salvarsan.

Case 2.—A young woman, aged 18, was examined by me June 24. The site of infection, which was on the right side of the upper lip, still showed some activity of the process. There was a circular, deep-red lesion about 1.5 cm. in diameter, with convexly elevated borders and a cicatricial depressed center. A slight induration was still present. Both of the submaxillary glands were enlarged, but the intumescence was greater on the right side. This patient was kissed several times by the offender March 18. On account of the appearance of his lip she permitted the liberty with reluctance and wiped her own lip afterward with a handkerchief. July 8 a Wassermann reaction was strongly positive. The patient was given an intravenous injection of salvarsan.

Case 3.—A young woman, aged 19, states that she developed a "sore" towards the end of April on her lower lip where she had had a fissure. The lesion was about twice the size of a pea. The maxillary glands and glands of the neck were enlarged. She consulted her physician and was placed on mercurial inunctions. When I examined her July 1 there was a split-pea-sized deep-red discoloration at the site of the chancre on the lower lip. A Wassermann reaction was strongly positive. She was given an intravenous injection of salvarsan.

Case 4.—A young woman, aged 16, first noticed a sore on her lip about April 13 and visited her physician one week later. She had a lesion on the left side of the lower lip which was diagnosed by the attending physician as a chancre. There was an enlargement of the submaxillary glands. She was placed on mercurial treatment. When I examined her but little of the lesion could be observed. A Wassermann reaction was strongly positive. She was given an intravenous injection of salvarsan.

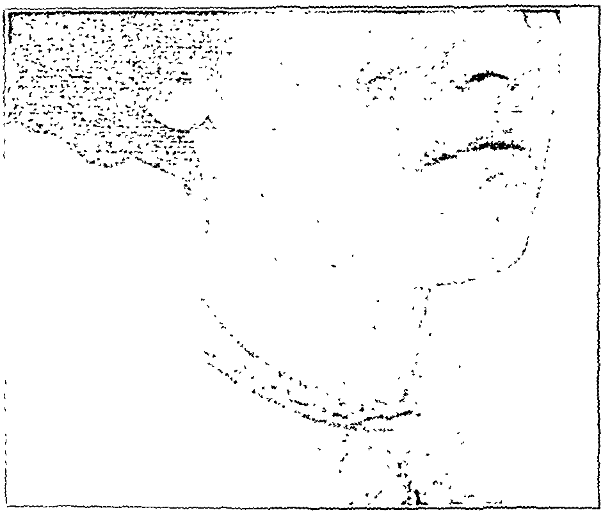
Case 5.—A young woman, aged 18, stated that her lip was noticeably sore about March 25. The lesion was situated on the right side of the lower lip and was never larger than a pea. It was crusted on the external half and covered with a whitish pellicle on the moist part of the lip. The lesion was properly diagnosed by her physician and the patient placed on mercurial treatment. When I examined her June 28 the site of the chancre was deep-red, shining and slightly elevated. The submaxillary glands were still somewhat enlarged.

Case 6.—A young man, aged 20, was present at the party and took part in the kissing games. In the early part of April he noticed a hard sore on the center of the upper lip. He states that he had the habit of biting his lip. His physician diagnosed chancre and placed him on mercury internally and sodium cacodylate hypodermically. When I examined him June 27 he exhibited the remains of the chancre on his upper lip. The lesion was convexly elevated, about the diameter of a cherry, and of a shining deep-red color. On the mucous aspect of the lip was a whitish pellicle. The maxillary and submaxillary glands on both sides were markedly enlarged. The patient stated that he had had a rash on the chest, but that this had disappeared. There was swelling and ulceration of the tonsils with mucous patches present. Spirochetes were found in the lip lesion and a Wassermann reaction was positive. An intravenous injection of salvarsan was given.

Case 7.—A young woman, aged 18, was not at the party referred to, but was kissed later by the same osculatory young man. Her physician informs me that she consulted him for a chancre of the lip which healed through the use of the biniodid of mercury.

Case 8.—A young woman, aged 18, was also infected. My knowledge of this patient is merely from hearsay, as I have not been able to see her. I am told by those who saw her that she had a very conspicuous sore on the lip in the early part of April. She stated that her physician "burned it out." She was at the party and was kissed several times by the young man with the labial chancre.

Five or six other young women at the several social functions were kissed by the young man with the labial chancre, without contracting syphilis. Of those who developed chancres, four had no knowledge of any abrasion on the lips prior to infection, one had a fissured lip, and one was in the habit of biting his lips. Of the seven chancres examined by me, four were on the lower lip, two on the upper, and in one case both lips were involved. In the case of the young man who contracted a chancre, there is reason to believe that he acquired the infection from virus deposited on the lips of one of the young women by the original disseminator. The source of the chancre of the lip in the original patient could not be definitely determined, but, inasmuch as the young man was given to frequent and promiscuous kissing, it is presumed that the disease was contracted in this manner.



Chancre of the cheek of several months' duration, presumably contracted indirectly from one of the young women with chancre of the lip.

Case 9.—Since writing the above I have been consulted by a 20-year-old young woman employed in the same establishment and brought into close contact with two of the patients with chancre of the lip, who presents a well-defined chancre on the right cheek below the malar bone. This first developed in April after the appearance of the labial sores in her associates. At the present time (July, 1911) there is a deep-red, firm, elevated placque about 1½ c.m. in diameter, with a slightly depressed cicatrical center. The submaxillary glands are enlarged. The patient and her physician state that she had some eruption on the trunk which disappeared under the administration of mercury. This patient handled telephone trunk cords which were used by the patient described in Case I. She states that she scratched a "pimple" on her cheek and the present lesion developed at the site. She was not kissed by the two young women with chancres of the lips, and had never come in contact with and, indeed, did not know the young man who was the source of the extragenital epidemic. The exact manner in which the infection was carried to this patient cannot be affirmed but it is reasonable to believe that it was derived from one of the young women with a lip chancre.

This most unfortunate epidemic should teach a lesson which cannot too strongly be impressed on the public, i. e., the danger of promiscuous kissing, either between those of the opposite or the same sex. This should be taught as a matter of every-day hygiene. In the second place, physicians must recognize that a tremendous responsibility rests on them in safeguarding the public from luetic patients under their care. Too often the instructions given to patients suffering from syphilis are perfunctory and unimpressive, if not omitted altogether. This epidemic likewise emphasizes the intense infectivity of extragenitally located chancres swarming, as they do, with spirochetes.

LINGUAL, SUBLINGUAL AND OTHER FORMS OF ABERRANT THYROIDS *

CHARLES H. MAYO, M.D.
ROCHESTER, MINN.

The common expression that "Man is as old as his blood-vessels" is no longer tenable. We now know that his growth and his manifest age depend more on the glands of the body which control function and metabolism, as well as the vessels themselves.

Inasmuch as the importance of the duct and the ductless glands is now known to us, we see why there should be, proportionately, so few anomalies among them in comparison with those in less important structures of the body.

It is becoming more and more apparent that of the various ductless glands the thyroid is one of the most important in its control of the body metabolism, as well as in the maintenance and stimulation of function in many of the associated glands. While various diseases or changes in its structure are fairly common, marked anomalies are exceedingly rare.

The first consideration in the study of the anomalies of this gland is the observation of development of the structure from the earliest embryonic stage. Usually the thyroid is considered as being developed from three anlage: the superior from the pharynx or mouth area is developed with the tongue which is in three portions: the anterior three-fifths, all in front of the circumvallate papilla, in fact, is formed from a median single body. The posterior two-fifths of the tongue is formed in halves, and at the center of union of these three portions, a tubular depression is developed with the bilobed thyroid anlage at its base, from which tissue the greater part of the gland is formed. As stated by most embryologists, this structure descends to unite at the seventh week with the lower anlage, one on either side, which has developed in the fourth branchial furrow. The hyoid bone is apparently developed at about the fifth week, and crosses the line of the descending thyroid.

The hyoid in its development entangles 40 odd per cent. of thyroids in their descent, causing a stringing out of the thyroid tissue to a variable degree. This portion, when present, is commonly known as the parimedial lobe and connects with the isthmus or the left upper pole.

The tube which developed as a consequence of the descent of the thyroid is known as the "thyroglossal

duct." It is lined with a temporary pharyngeal epithelium, and apparently is a phylogenetic remnant of the excretory duct of the thyroid which still persists in certain of the invertebrate animals; for example, the sea scorpion, the limulus or king crab, etc., in which, the thyroid being a true sex gland, the duct empties into the uterus or the genital tract (Gaskill). This duct is not lined with thyroid epithelium in man, but with fetal pharyngeal mucosa which undergoes obliteration more or less completely, the remains of its upper extremity being marked by the depression or opening at the back of the tongue, known as the "foramen cecum." In anomalies in which there is a failure of obliteration of this duct, or in which portions of true pharyngeal mucosa are carried down by it, are found the midline cysts of the upper cervical region. These are not true branchial cysts, but thyroglossal duct cysts filled with mucoid material. Being remnants of the embryologic development, they retain power of generation and growth when operated on unless every vestige of the structure is removed. In several cases we have seen such cysts open through a delicate foramen in the center of the hyoid bone where it had been grapsed by the developing hyoid.

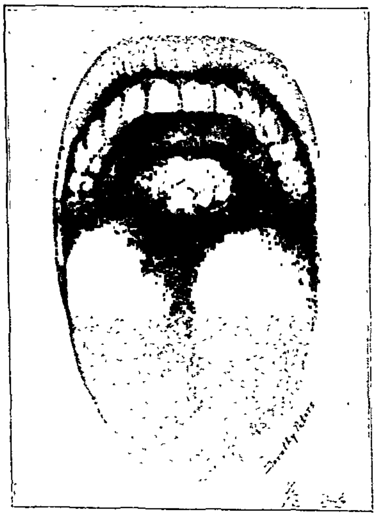

Fig. 1.—Lingual thyroid.

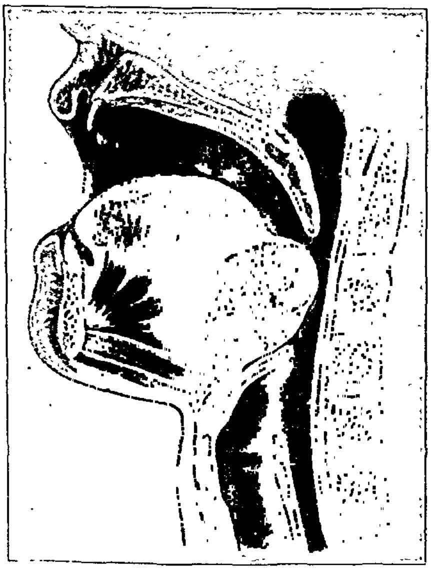

Fig. 2.—Lingual thyroid seen in cross section.

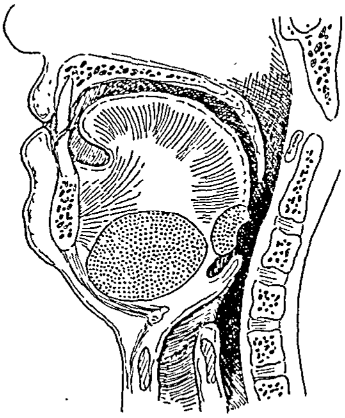

Fig. 3.—Lingual and sublingual thyroids. (From Priestly Leech, *The Medical Annual*, 1906.)

It may be seen readily then, that a delayed descent of the thyroid from its lingual position, or an early formation of the hyoid, might force the development of this portion of the thyroid into the lingual or the sublingual area.

His, and other embryologists, formerly believed that the lower poles of the thyroid were developed in the fourth branchial grooves, but in His' later work he is more doubtful concerning this point and is inclined to believe, with some others, that there is a possibility of these lower centers developing tissue which later disappears, but which resembles the so-called suprapericardial bodies of the vertebrates. However, if it is true that these bodies are thyroids, it would explain some of the anomalies of the lower portion of the gland; for example, aberrant or accessory thyroids beneath the sternum or within the upper chest. Such tissue might occasionally be dragged to this position by the thymus gland, which forms one notch higher, namely, in the third furrows, and descends to a point behind the sternum.

Thyroid tissue completely separate from the rest of the gland is usually described as aberrant, while if it is at all connected with the main thyroid it is called an accessory thyroid. The anomalies of the lower portion of the gland are fairly common, being seen probably once in fifty thyroid operations for simple goiter. Aberrant thyroids, found laterally, we have observed with much less frequency. Small accessory and aberrant thyroids between the hyoid and isthmus of the thyroid are relatively common.

I have seen but three lingual thyroids; one in a boy of 18 years, in whom the growth had been present for six years; one in a woman of 46, which had been noticed for several years, and one in a woman of 63, which had been present about two years (Figs. 1 and 2). The latter case presented both types of lingual and sublingual; the superior upper portion was the size of a large walnut, while the inferior lingual tumor was nearly as large.

In corroboration of the views of those embryologists who believe that the bulk, if not all, of the thyroid has developed from the pharyngeal anlage, it is of interest to note that in approximately one in seven of the cases, patients operated on for lingual thyroid develop myxedema. It is probable that some cases were reported too early after operation to give any accurate information in regard to this point, and that in others only the cystic portion was enucleated, leaving a part of active thyroid.

I believe that a careful examination of the thyroid region should be made before operation in order that a less extensive removal of tissue will be made if there is no palpable thyroid, treating the tumor by shelling out the cyst interior rather than by the more radical removal of all the tissue.

It is very probable that stray portions of the thyroid are of frequent occurrence and are not recognized since there may be no pathologic change occurring in the aberrant portion to make its presence known by tumor formation.

In the diagnosis, the suprahyoid or the midline tumors must be differentiated from malignant disease of the glands of undiscoverable primary origin, from thyroglossal duct cysts, from dermoids, ranula, lingual tonsils, etc. In some instances this will be determined only by operation.

Free hemorrhage has been noted as a symptom in some of the reported cases. The thyroids in the tongue, as seen in the supralingual, are usually rounded tumors covered with thin mucosa with numerous veins coursing over the surface. Their prominence is between the epiglottis and the foramen cecum (Fig. 3). The slowness of the growth, in consideration of the richness of the blood-supply in this area, usually eliminates malignancy. Angiomas are differentiated by being more spongy, more irregular in outline, of purple color and usually showing venous extension to one of the lateral pharyngeal areas.

When tumors are found in the lingual and the sublingual positions in the same patient they may be removed, if preferred, in two stages, first, from a hyoid transverse incision with separation of the muscles, similar to ordinary goiter operations (this operation leaves less scar than the vertical); later, enucleation of the upper portion from the tongue, as was done in our third case.

In the enucleation of lingual thyroids the tongue and pharyngeal areas are cocainized, the patient anesthetized with ether and a rapid operation made while the tongue is held in extreme tension. The free hemorrhage is controlled by deep sutures. In very extensive superior lingual goiter it may be advisable occasionally to ligate the lingual arteries and make a laryngotomy as a preliminary procedure. It will rarely be necessary to divide and separate the lower jaw.

While the operations for the removal of lingual thyroids through the mouth have been quite bloody, they have been successful; practically no fatalities have been reported. Although there have been approximately but fifty cases recorded, undoubtedly there have been many others in which patients have been operated on.

CASE 1.—A woman, aged 46, came for examination in 1893. There was a tumor on the dorsal posterior surface of the tongue. An operation was performed under local and general anesthesia A blunt dissection was made and the cystic colloid thyroid was removed. Recovery followed.

CASE 2.—J. D., male, aged 18, was admitted to the hospital, June 1, 1896. An examination showed a blood-tumor at the base of the tongue of about six years' standing. The patient spoke with difficulty. The diagnosis was: A tumor on the posterior part of the tongue next to the epiglottis. The operation consisted in making a temporary division of the jaw at the symphysis of the tongue and in excising the growth. Recovery followed. Pathologic report was "adenosarcoma."

CASE 3.—Mrs. J. W. H., aged 63, on examination Nov. 15 1910, was found to have a growth at the base of the tongue, which had been first noticed as a small lump eighteen months before. Two months previously the growth had become noticeable and troublesome, because of a feeling of fulness. There was no pain, but there were headaches after any exertion. A tumor was found in the posterior one-third of the dorsum of the tongue, the size of a hen's egg. There was a subcutaneous tumor (slightly smaller) under the chin. The diagnosis was of lingual thyroid.

Nov. 21, 1910, the operation, consisting of the enucleation of the lingual thyroid from the submental region, was performed, and two weeks later the superior lingual tumor was removed through the mouth. Recovery followed. Pathologic report was "aberrant thyroid with bone deposit."

Unclean Operators.—Each pitiful, infected, suppurated, fever-burned, doctor-poisoned victim, remarks Dawbarn in the *Medical Record*, like a gaunt specter, brings back to our thoughts with hideous clearness what surgery was before the surgeon knew better. He knows better now. To-day the man who operates unclean of person or appliance is unclean of soul.

THE TREATMENT OF LATERAL CURVATURE OF THE SPINE

ROBERT W. LOVETT, M.D.
AND
JAMES WARREN SEVER, M.D.
BOSTON

For many years the treatment of lateral curvature has been considered a muscular problem to be met by muscular therapeutics, that is, by gymnastics. Although this treatment has been on the whole successful when properly carried out in the functional and milder structural types of the affection, it has been on the whole distinctly unsuccessful in the treatment of the moderate and severe types of scoliosis. The reason for this is that the treatment of the severer types of the affection is a bone and not a muscle problem, and must be carried out by means of sound surgical principles addressed to the reshaping of distorted bone. The treatment to be advocated in the present paper is based on these principles, and the results of the treatment are shown as carried out for three years in the lateral curvature clinic of the Children's Hospital, Boston.

There are two varieties of lateral curvature, (1) the postural or functional, and (2) the organic or structural. The first variety can be quickly discussed and laid aside, for it is the second variety which constitutes our real problem.

FUNCTIONAL OR POSTURAL LATERAL CURVATURE

The former is really nothing but a faulty attitude, and the latter would be a better name for it. The child, who is generally from 5 to 15 years old, stands with a slight or very moderate lateral curve of the whole spine, in most instances to the left. The left shoulder is higher than the other, and the trunk is displaced to the left, uncovering the right iliac crest and making it more prominent than the left. There is no marked rotation or twisting of the curved region, but when the child bends forward from the hips and the trunk becomes horizontal, the right side of the back of the thorax can be seen to be very slightly higher than the left. The curve disappears when the patient lies down.

The condition is often associated with round shoulders and round back, and where statistics have been taken regarding it, it has been found to occur in from 20 to 25 per cent. of children of school age. The curve is always single, and compensatory curves do not exist. It is sometimes described as total scoliosis, which should be interpreted as being synonymous with functional or postural scoliosis.

Two mistakes are frequently made in dealing with this condition. In the first place, the curve is so slight that it is frequently overlooked, and second, if it is recognized, the parents are frequently told that the child will outgrow it. There is no reason for overlooking the existence of any postural curve, because it is perfectly simple to hang a plumb-line in the cleft of the buttocks and see if the spinous processes form a straight line and come under that plumb-line. If they deviate in a gradual curve, total scoliosis exists.

With regard to the second point, so far as observations go, there is no tendency to the spontaneous outgrowth of the condition. It is extremely common in adults, and the tendency of growth is entirely toward an increase of the deformity rather than toward a straightening of the spine. Such cases frequently change to the structural type in the process of growth, double curves forming out of single ones; but such cases do not as a rule change to the severe type of structural curve, so that having recognized the existence of a postural lateral curve, the parents should be told that it will probably increase somewhat, will undoubtedly persist into adult life unless efficiently treated, but will probably not cause serious or disabling deformity.

TREATMENT

The treatment is simple. The general hygiene should be looked into, overwork at school and at home prevented, and if the resistance of the child is below normal the day should be shortened slightly by a period of recumbency during the day.

The question of clothes is an important one and should be investigated. Most children of this age wear a waist with shoulder straps which rest near the tips of the shoulders. To this waist are attached the clothes, and also side elastic garters running to the stockings, which are kept very tight. The tension of these elastics is transmitted by the waist to the straps over the shoulders, and the shoulders are continually pulled downward and forward. Round garters should be substituted for side elastics in these cases, the clothes suspended from the waist should be as light as possible, and in many instances they may be supported from a belt.

If there is any reason to suspect a visual error leading to an improper position in reading, the eyes should be examined and such error corrected. It is advisable in all instances to go into the question of a short leg, not by a measurement from anterior superior spine to the internal malleolus, which is of little practical value and often misleading, but by placing under the foot on the side to which the spine curves enough pamphlets to raise the pelvis on that side and see if an improved position of the spine results. If it does, a higher sole should be worn on that side with a view to inducing a constant improvement in the spinal position.

With these preliminaries taken care of, the treatment should consist of a special set of gymnastics which are within the range of any good teacher of gymnastics, consisting practically of a setting-up drill similar to that given to army recruits. Such patients should exercise daily for half an hour or an hour under the supervision of the teacher until they can maintain a symmetrical position for a few minutes, when they can be allowed to do the exercises at home under the supervision of a parent, and report for observation. The gymnastic work should be individual and class work discouraged.

The daily active treatment should generally not cover a period of more than from one to three weeks under favorable conditions, but the observation period should last for at least a year. Under these conditions the prognosis for a complete cure is excellent, but exercises must be done with precision and vigor, and the general condition of the child must be regarded.

These cases may then be dismissed from our consideration and we can pass to our real problem—the treatment of structural lateral curvature.

ORGANIC OR STRUCTURAL LATERAL CURVATURE

This is accompanied by changes in the spinal structure, with deformity in the vertebræ. The phenomena cannot be reproduced experimentally, and the condition is outside of the normal behavior of the spine and implies structural change. Severe cases in childhood are due to one of five causes.

1. A congenital anomaly of the spine, such as split vertebræ, defective ribs, etc., a class of cases only recently recognized as so important, and until the general use of the x-ray not generally understood.
2. Infantile paralysis.
3. Empyema.
4. Rickets.
5. A softness of the bones which we must assume without direct evidence of rickets, but in which bony deformity is so great that it is evident that the bony resistance is below the normal.

The characteristics of organic lateral curvature are definite curves, either single or double—more often the latter—and much more marked than in the postural class, in some cases running to extreme deformity. There is always a rotation of the vertebræ or horizontal twist at the site of the curve, and in bending forward, with the trunk horizontal and the arms hanging, there is always to be seen a more or less marked upward bunch or prominence in the affected region on the side to which the spine curves, that is, on the convex side of the lateral curve. If the curve is double, there are two rotations corresponding to the two curves. This is a constant characteristic, and is diagnostic of this type of curvature. A right curve has always a right prominence and *vice versa* on the other side. The curve does not disappear on lying down, and the x-ray shows a deformity of the vertebræ, with compression of the intervertebral disks on the concave side, and in the more advanced cases, with a wedge-shaped deformity of the vertebræ. Distortion of the figure, the elevation of one shoulder, the prominence of one ilium, a general displacement of the body to the side, etc., are the results and expression of this bony spinal deformity.

It must be clearly recognized that these are the cases that present the difficulty in treatment, the vertebral column in these cases being deformed to some extent, with the changes mentioned, namely, shortened ligaments and muscles, compressed disks, and, in the severe cases, wedge-shaped vertebræ. In addition to these deformities to the side, the vertebræ twist on a vertical axis and are thus distorted along with the ribs and the bony structures of the thorax, which share in the deformity in severer cases. These changes in the lateral and in the horizontal direction result in distortion of the viscera, compression of the lungs, displacement of the heart and disturbance of the abdominal viscera, which in severe cases predispose to impaired digestion, deficient chest capacity, and in general to impaired resistance, so that it is safe to say that as a rule patients with severe scoliosis in adult life are badly nourished and have an impaired resistance. Extreme deformity may result in the severest cases.

TREATMENT

Having thus defined very briefly the essentials of the condition, we come to the very difficult question of how such cases should be treated. As the keynote of the treatment to be advocated, we must recognize that bone is an adaptive structure, and in its growth follows the line of least resistance, and we must remember also that we are dealing with a lateral bony deformity of the spine. Putting these two considerations together, it would seem as if our best chance of remedying the bony deformity was to force the spine into as normal a position as can be obtained, and to hold it in that position during part of the period of growth. This is, in brief the treatment that will be advocated.

The majority of such cases in this country, as a matter of fact, are at present treated by gymnastics, and one rarely sees a bad case in which this treatment has not

Figure 2

[illegible]

from the [illegible]

[illegible] general surgical [illegible] as follows [illegible] exists between [illegible] child of [illegible] an hour's [illegible] or other [illegible] gravity [illegible] Our knowledge [illegible] would not allow us [illegible] is allowed and [illegible] the spine [illegible] treatment in [illegible] good, but [illegible] a certain [illegible] the same [illegible] position. A spine with severe lateral [illegible] a treatment analogous to that universally recognized as effective in the cure of congenital club-foot, namely, securing a proper position of the deformed structures and maintaining this position until the bones are reshaped by growth. In the treatment to be advocated for this grade of lateral curvature, no more attention in the beginning is paid to the muscles than is the case in the treatment for club-foot, which is a radical departure from accepted views.

A curious experience directed our attention to the possibility of this method. A girl with severe lateral curvature applied at the Children's Hospital for treatment. A forcible plaster jacket was applied and an *x*-ray of the spine in the corrected position taken through windows cut in the jacket. The girl was instructed to return in two weeks to have the jacket changed. Instead of returning in fourteen days, she stayed away fourteen months and came back wearing the same jacket. The improvement in her position at the end of this time was extraordinary, and an *x*-ray of the spine taken at the second visit showed an improvement in the bony curve. This suggested a treatment which has been followed out in modified form during the last three years.

For moderate and severe structural lateral curvature the treatment is of two kinds, either (1) by the use of a permanent corrective jacket worn for long periods, or (2) in its modified form by the use at first of a corrective jacket followed by a removable jacket and exercises.

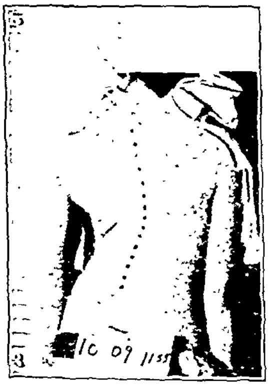

Fig. 4.—Girl aged 16, before treatment.

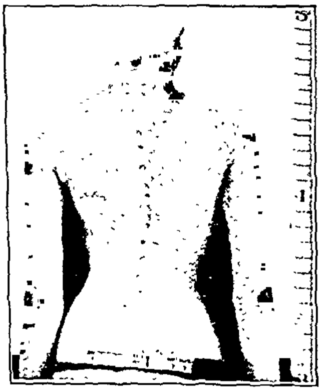

Fig. 5.—Girl aged 17, after fourteen months' treatment by removable jackets without exercises.

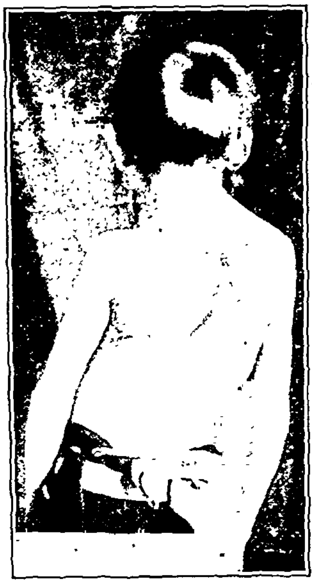

Fig. 6.—Boy aged 12, before treatment.

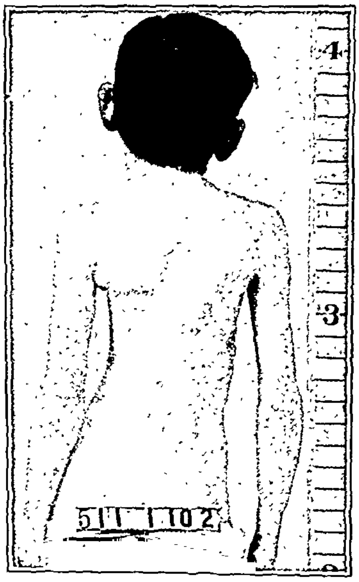

Fig. 7.—Boy aged 14, after two years' treatment by means of permanent jackets.

Permanent Jackets.—The first form, the permanent forcible jacket, is better suited to hospital practice than the other. We have for two years been taking cases of similar grades in the clinic and treating some by one method and some by the other, as a result of which we have come to the conclusion that the treatment by permanent jackets produces better results. The treatment by permanent jackets is as follows: Either in recumbency or in suspension a jacket is applied to the patient, securing the best obtainable position without the use of high degrees of force. At first we used the recumbent position with considerable amounts of force, but in hospital practice sloughs occurred, and if much force was used, occasionally trouble with respiration followed, and experience has shown us that we can obtain the same efficiency without the risk by the use of smaller degrees of corrective force in the initial jacket put on in suspension.

When the jacket is hardened, it is left solid over the parts that are made prominent by the rotation behind and in front, that is, in a right dorsal curve the right back and left front are not touched, but large windows are cut over the depressed side of the chest behind and the corresponding portion diagonally opposite in front, so that in a right dorsal curve the left side would be cut out behind and the right side in front. This makes it possible for the depressed parts of the chest to be expanded by respiration, while the prominent parts are compressed. Pads of felt are now inserted between the prominent part of the chest behind and the jacket, and sometimes in the corresponding region in the front, thus making the jacket more corrective, and thicker pads are substituted each week without changing the jacket, these being drawn through without difficulty by means of a bandage. In this way, a continual diagonal side-pressure is kept up on the curved portion of the spine and is steadily increased. At the end of two or three months, it will be found that it is advisable to apply a new jacket, to cut it out in the same way and to begin on the progressive padding. The use of such a permanent jacket is continued for a period of from one to two years, being changed at long intervals, and at the end of this time a removable jacket is substituted for the permanent one and gymnastic treatment is begun. The removable jacket is then gradually discontinued while the patient's muscular condition is being improved by gymnastic exercises.

Removable Jackets.—As in the former method, the second treatment, that by removable jackets, is started by the application of a forcible jacket either in recumbency or suspension. This is followed by a second jacket at an interval of a week. After the application of the second jacket, the patient is suspended and a plaster jacket is applied which is immediately cut off to serve as a mold, and a third forcible jacket is applied to be worn while the removable apparatus is being made. The jacket which is to serve as a mold is then bound together and filled with plaster of Paris and water, a torso thus being obtained. This torso is then remodeled by cutting off on the prominent side and building up on the other side, until it has become decidedly more symmetrical than the patient. It is also sawed in halves at the waist and set apart about an inch in order to secure continued extension.

already been pursued and has failed. There are, apparently, two reasons for this. First, the treatment by pure gymnastics is inadequate for any but slight and moderate cases, and therefore unsuited to the treatment of severe cases, and second, in general it is ineffectually given, because the average medical gymnast thinks if he gives a treatment which he has reason to believe is proper, his responsibility ends; he does not measure the efficiency of his treatment by the results. If gymnastic treatment is to be given for cases of more than slight grade, let it be given as it is in Europe, where a patient goes to an institute and lives, abandoning school and family, works for several hours a day in specially constructed apparatus, spends perhaps hours in a recumbent position, and pursues this treatment for month after month under the supervision of skilled assistants. Under these conditions one may expect results from gymnastic treatment in properly selected cases; but contrast that treatment with what is generally given here as the gymnastic treatment, an exercise period perhaps three times a week with the patient under no supervision in the meanwhile and wearing no apparatus, the treatment interrupted by home demands, illness and other conditions, followed out in a half-hearted way for some months and finally abandoned. It is not reasonable, under these conditions, to expect much from the gymnastic treatment.

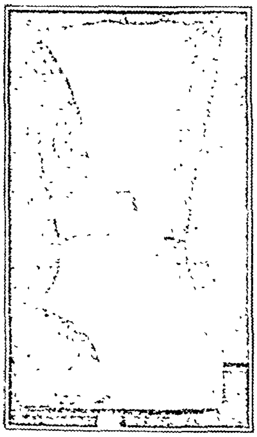

Figure 1.

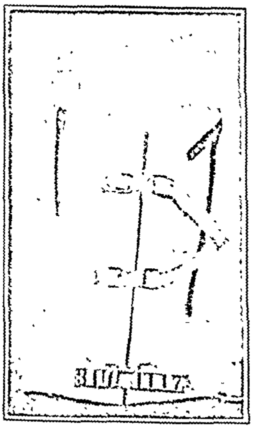

Figure 2.

Fig. 1.—Remodeled torso ready for application of jacket, in a case of right dorsal left lumbar scoliosis which has been cut in two at the waist and set apart 1 inch, so as to increase the upward pressure on the ribs. The dark areas on left of the torso show where plaster has been added on the concave side to allow for correction of displacement and deviation.

Fig. 2.—Front of jacket made over torso shown in Figure 1. Note shoulder pad.

If we look at the facts from a general surgical point of view, the condition seems to be as follows: A deformity analogous to knock-knee exists between each two vertebræ. We would not in a child of 8, for example, expect to cure knock-knee by an hour's muscular exercise given three times a week or oftener, while the rest of the time, except during sleeping, gravity is at work to exaggerate the condition. Our knowledge of the principles of general surgery would not allow us to sanction such a treatment, but it is allowed and sanctioned in an analogous deformity affecting the spine.

Moreover, not only does gymnastic treatment in the severe grade of cases as a rule do no good, but if effectually carried out, it does harm up to a certain point by loosening up a stiff spine and allowing the spine to sag farther into the bad position. A spine with severe lateral curvature soon becomes stiff and gets slowly worse, but if it is loosened by effective gymnastics, the side thrust of the superincumbent weight is so great that it becomes rapidly worse and the patient's average standing position is worse than before treatment was begun.

The rule should be, therefore, either (1) not to use gymnastics alone in any but slight cases, (2) to keep the patient recumbent until the gymnastics have developed muscles as well as restored flexibility, or (3) to use a support in connection with gymnastics to hold the improved position.

The use of gymnastics alone in lateral curvature of the spine should be limited to the slighter grades of structural curves. Such gymnastics should obviously have two aims, (1) to restore flexibility, and (2) to cultivate the holding power. The exercises should be done with vigor and precision for at least an hour daily, and they are to be regarded as effective only so long as they produce manifest improvement. Gymnastic treatment should be stopped temporarily if the patient loses weight, becomes irritable or languid, or if the menstruation in girls becomes profuse. The gymnastics to be used are to be found in the text-books on orthopedic surgery and in certain French and German books devoted to the subject.[1] Until the medical profession insists on the adequate and careful performance of gymnastic treatment and limits it to suitable cases it will fall into even greater disrepute than now.

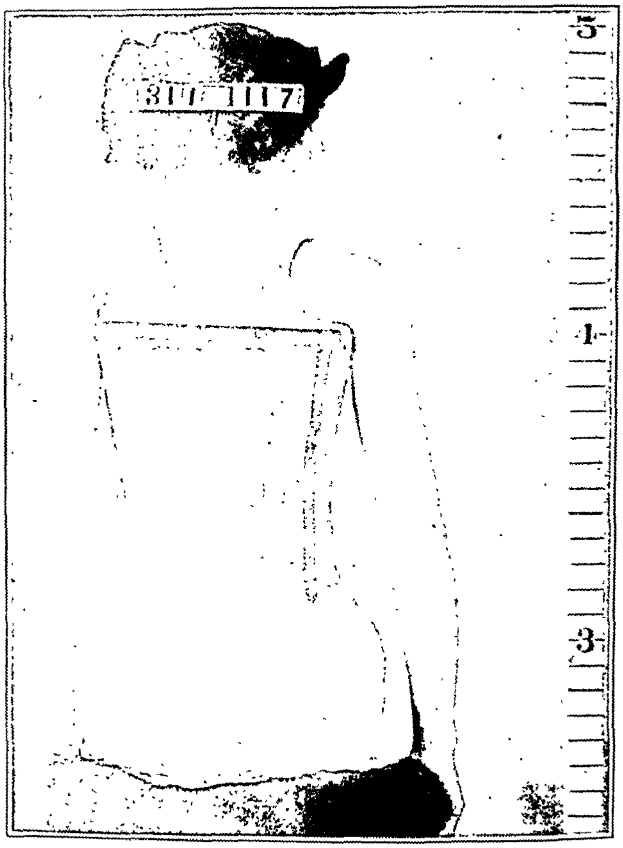

Fig. 3.—Patient in jacket shown in Figure 2. Note window on concave side. Jacket reinforced by steel strips.

Recognizing then the need of attacking moderate and severe lateral curvature as a bone problem, we advocate

---

a treatment analogous to that universally recognized as effective in the cure of congenital club-foot, namely, securing a proper position of the deformed structures and maintaining this position until the bones are reshaped by growth. In the treatment to be advocated for this grade of lateral curvature, no more attention in the beginning is paid to the muscles than is the case in the treatment for club-foot, which is a radical departure from accepted views.

A curious experience directed our attention to the possibility of this method. A girl with severe lateral curvature applied at the Children's Hospital for treatment. A forcible plaster jacket was applied and an x-ray of the spine in the corrected position taken through windows cut in the jacket. The girl was instructed to return in two weeks to have the jacket changed. Instead of returning in fourteen days, she stayed away fourteen months and came back wearing the same jacket. The improvement in her position at the end of this time was extraordinary, and an x-ray of the spine taken at the second visit showed an improvement in the bony curve. This suggested a treatment which has been followed out in modified form during the last three years.

For moderate and severe structural lateral curvature the treatment is of two kinds, either (1) by the use of a permanent corrective jacket worn for long periods, or (2) in its modified form by the use at first of a corrective jacket followed by a removable jacket and exercises.

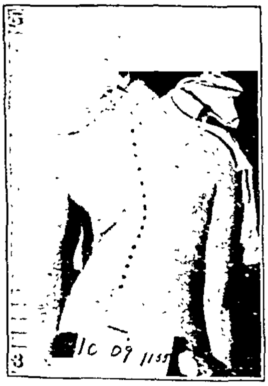

Fig. 4.—Girl aged 16, before treatment.

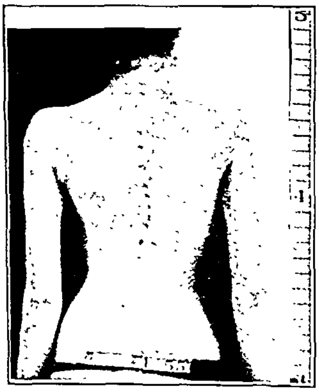

Fig. 5.—Girl aged 17, after fourteen months' treatment by removable jackets without exercises.

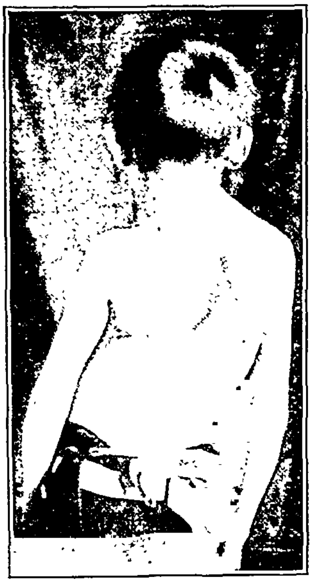

Fig. 6.—Boy aged 12, before treatment.

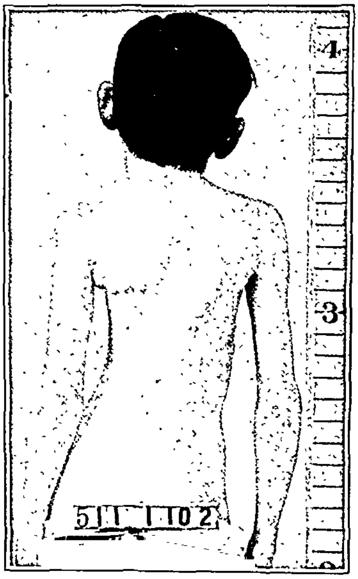

Fig. 7.—Boy aged 14, after two years' treatment by means of permanent jackets.

Permanent Jackets.—The first form, the permanent forcible jacket, is better suited to hospital practice than the other. We have for two years been taking cases of similar grades in the clinic and treating some by one method and some by the other, as a result of which we have come to the conclusion that the treatment by permanent jackets produces better results. The treatment by permanent jackets is as follows: Either in recumbency or in suspension a jacket is applied to the patient, securing the best obtainable position without the use of high degrees of force. At first we used the recumbent position with considerable amounts of force, but in hospital practice sloughs occurred, and if much force was used, occasionally trouble with respiration followed, and experience has shown us that we can obtain the same efficiency without the risk by the use of smaller degrees of corrective force in the initial jacket put on in suspension.

When the jacket is hardened, it is left solid over the parts that are made prominent by the rotation behind and in front, that is, in a right dorsal curve the right back and left front are not touched, but large windows are cut over the depressed side of the chest behind and the corresponding portion diagonally opposite in front, so that in a right dorsal curve the left side would be cut out behind and the right side in front. This makes it possible for the depressed parts of the chest to be expanded by respiration, while the prominent parts are compressed. Pads of felt are now inserted between the prominent part of the chest behind and the jacket, and sometimes in the corresponding region in the front, thus making the jacket more corrective, and thicker pads are substituted each week *without changing the jacket*, these being drawn through without difficulty by means of a bandage. In this way, a continual diagonal side-pressure is kept up on the curved portion of the spine and is steadily increased. At the end of two or three months, it will be found that it is advisable to apply a new jacket, to cut it out in the same way and to begin on the progressive padding. The use of such a permanent jacket is continued for a period of from one to two years, being changed at long intervals, and at the end of this time a removable jacket is substituted for the permanent one and gymnastic treatment is begun. The removable jacket is then gradually discontinued while the patient's muscular condition is being improved by gymnastic exercises.

Removable Jackets.—As in the former method, the second treatment, that by removable jackets, is started by the application of a forcible jacket either in recumbency or suspension. This is followed by a second jacket at an interval of a week. After the application of the second jacket, the patient is suspended and a plaster jacket is applied which is immediately cut off to serve as a mold, and a third forcible jacket is applied to be worn while the removable apparatus is being made. The jacket which is to serve as a mold is then bound together and filled with plaster of Paris and water, a torso thus being obtained. This torso is then remodeled by cutting off on the prominent side and building up on the other side, until it has become decidedly more symmetrical than the patient. It is also sawed in halves at the waist and set apart about an inch in order to secure continued extension.

On this corrected torso a plaster jacket is applied which is to be the removable jacket worn by the patient. This removable jacket should be supplied with shoulder pads to hold the shoulders in position, and should open down the front, being supplied with buckles and straps or lacings. It may also be advisable to slash such jackets over the iliac crests. The addition of 5 per cent. Portland cement to the plaster with which the jacket is made gives greater strength and durability. This jacket is to be worn by the patient night and day and to be removed only for the exercise period, which should consist of one hour or more daily, the exercises being of the type mentioned above. When the jacket is applied, it is sprung open and slipped on the patient, who then lies on the back, and the arms and legs are pulled on to extend the spine. It is then buckled tightly in place before the patient stands up.

Jackets of either kind should be tested for efficiency by measuring the height of the patient with and without the jacket. Without the jacket the patient places the hands on the hips and pushes up, making himself as tall as possible, and his height is taken in this position. The jacket is then applied and the patient's height is again taken. If the jacket does not hold him in as good a position, as estimated by height, as the patient can possibly assume with the hands on the hips, it is discarded and a more corrective one is made. In these jackets it is often advisable to cut the windows as in the permanent form, and to use padding in addition to the correction of the torso.

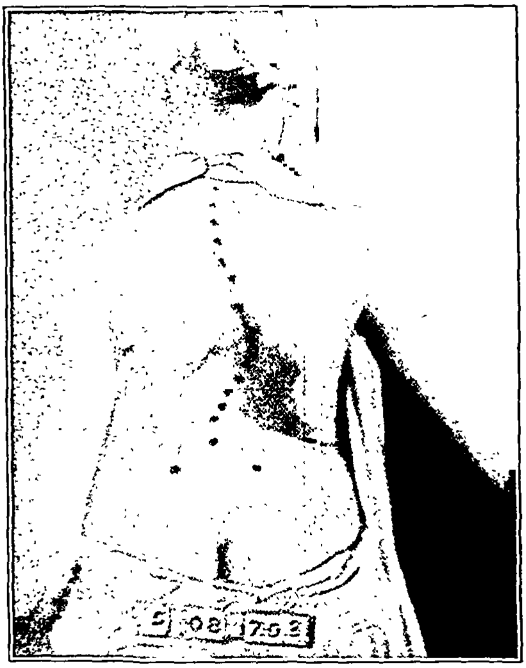

Fig. 8.—Girl aged 16, before treatment.

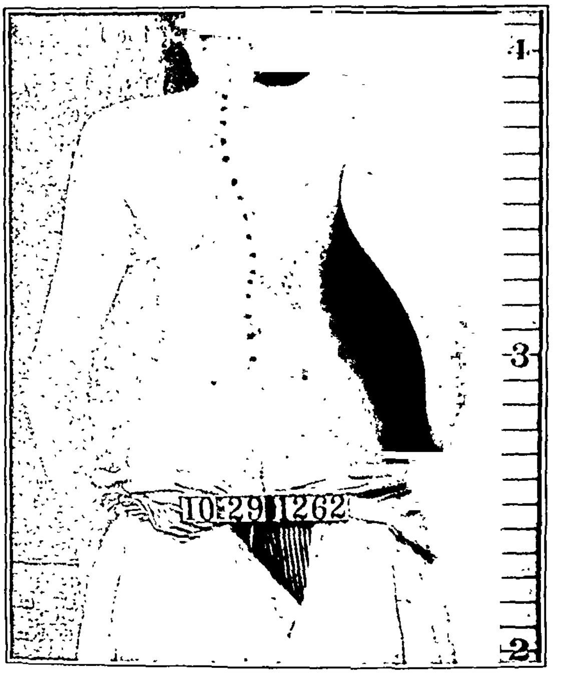

Fig. 9.—Girl aged 18, after two and one-half years' treatment by means of a series of permanent jackets.

If such a jacket is worn by a patient who is making good progress, in a few weeks from the beginning of treatment it will be found to be inefficient and not to be holding him on account of his improvement. Under these conditions the torso must be again remodeled, more cut away from the prominent side and greater pressure exerted. In the course of a year, probably two or three such remodelings would be required. These jackets may be made of leather or celluloid if preferred rather than plaster, but the plaster is perfectly efficient, although heavier.

This treatment is more acceptable than the former to private patients, and where the patient is under complete control, it is probably nearly as efficient as the other, although perhaps taking a little longer time. When such treatment as the latter has been continued over a period of a year or more in the severer cases, a trial may be made of removing the jacket for a short period each day and watching the patient during this period, the jacket being gradually abandoned as the patient's corrective power increases. In neither form of treatment in severe scoliosis is the treatment likely to last less than two years, although in the moderate forms it may take less time to secure the desired results.

Finally, it may be well to meet two criticisms which are likely to be made. In the first place, the results are presented by photographs, patients unconsciously pose, shadows distort, and the method is not scientifically accurate. At the same time, in this clinic we have tried many other methods of measurement, including the Schultess machine for recording lateral curvature, and after a careful trial of each we have returned to photographs as, on the whole, the most reliable and practical method of presenting results.

In the second place, the criticism will be made that the results that we show are not necessarily permanent. This treatment has been used by us, for too short a time for us to be able to produce in this series, definite evidence that the results are permanent. In answer to this criticism, it can only be said that bone is an adaptive structure; that we have seen a change in the bony curve under this treatment as demonstrated by the *x*-ray; that the Chinese woman's foot is deformed permanently by pressure; that the shape of the bones in club-foot is permanently altered and restored to normal by pressure: that experimentally, bony lateral curvature was produced by Wullstein in dogs; that in the cases under observation longest the results have tended to be permanent, and finally, that Schanz of Dresden from a similar treatment has shown the persistence of good results for one or two years after the cessation of treatment. It is possible to state that if the treatment is stopped half way, immediate relapse follows and nothing is gained, but if the treatment is persisted in until the end and gradually discontinued, it seems likely that the results obtained will be permanent.

MILD CASES OF HOOKWORM DISEASE IN CHILDREN

THOMPSON FRAZER, M.S., M.D.
ASHEVILLE, N. C.

One of the first results of the systematic study of any disease is the discovery that, in addition to the so-called typical cases, there are many others so mild in character that they are at first entirely overlooked. To many, no doubt, hookworm disease at once suggests a picture of extreme pallor and emaciation, with considerable edema and a hemoglobin percentage of thirty or under; it is less well known that one may harbor hookworms and that their presence may be entirely unsuspected. After the removal of the worms by a course of thymol, the patient will often gain rapidly in weight and strength (and, if a child, in height), showing that, though the effect of the parasites on nutrition is at times slight, it should not be disregarded.

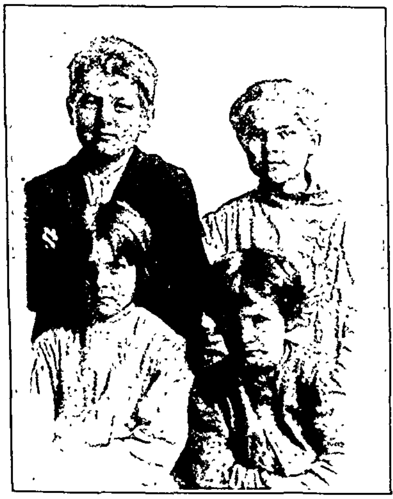

Fig. 1.—Four children of one family treated for hookworm disease. These children show little evidence of symptoms of the disease.

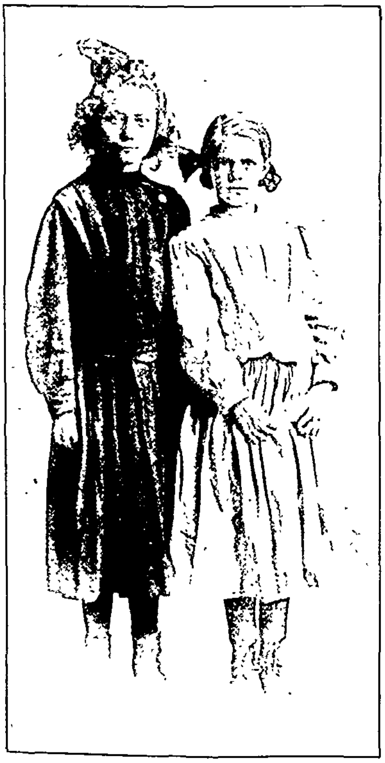

Fig. 2.—Two girls treated for hookworm disease. The taller is 11 years of age; the smaller girl, who is much stunted in growth, is 15 years of age.

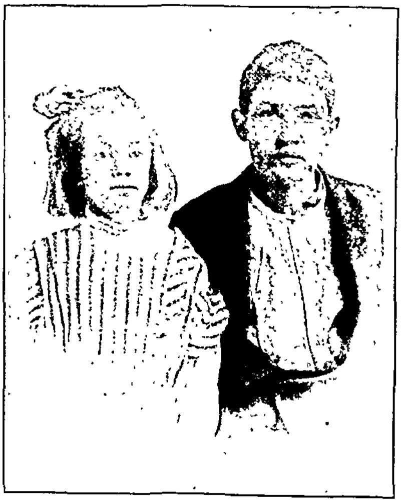

Fig. 3.—Two victims of hookworm disease whose symptoms are more marked than those of the other children shown.

I present the pictures of a few of the children treated this winter and spring for uncinariasis at the Asheville Free Dispensary. I have purposely selected the milder cases.

Figure 1 shows four children of one family; they are, respectively, 3½, 6, 8 and 12 years of age. The two larger children are quite healthy in appearance, the others although not so robust do not appear sickly. The size and weight of each compares favorably with the norm. In none of them were there digestive disturbances, edema or pallor; and the hemoglobin ranged between 85 and 95 per cent.

Figure 2 is of interest in that some of the more characteristic features of the disease are shown. The taller girl, aged 11, is not undersized and might have been included in the first picture but for a somewhat sickly expression and a languid manner. The smaller girl, nearly 15 years of age, is very much stunted; the breasts are undeveloped and the mentality low. Note the prematurely aged expression of her face.

In Figure 3, the appearance of ill health is more marked. The boy, aged 16, has a heavy, stupid expression, and has suffered with headache and "stomach trouble" for several months. The little girl, aged 10, is dwarfed mentally and physically, she takes no interest in her studies, does not care to play and seldom smiles. The hemoglobin percentage of those shown in Figures 2 and 3 was between 65 and 80.

All of the children that I have been able to follow up have shown marked improvement in a few weeks. I gave them from one to three thymol courses and then put them on Blaud's pills and the results have been more than satisfactory. The teachers testify that after the thymol treatment many of the youngsters were transformed from dullards into normal, mischievous children.

A NEW PROCTOSCOPE AND SIGMOIDOSCOPE

DUDLEY ROBERTS, M.D.
BROOKLYN, N. Y.

Those who have used the various types of proctoscopes and sigmoidoscopes know that each has certain advantages and disadvantages. The instrument known as the Kelly tube, depending on a headlight for illumination, is the simplest and cheapest. With it the upper rectum and sigmoid are often examined with great difficulty. The examiner is forced to assume an exceedingly awkward position in order to line up his eye, the light and the long tube. Instrumentation with this method of illumination is difficult, as the instrument and hands interfere with the light. The light cannot be satisfac-

On this corrected torso a plaster jacket is applied which is to be the removable jacket worn by the patient. This removable jacket should be supplied with shoulder pads to hold the shoulders in position, and should open down the front, being supplied with buckles and straps or lacings. It may also be advisable to slash such jackets over the iliac crests. The addition of 5 per cent. Portland cement to the plaster with which the jacket is made gives greater strength and durability. This jacket is to be worn by the patient night and day and to be removed only for the exercise period, which should consist of one hour or more daily, the exercises being of the type mentioned above. A NEW PROCTOSCOPE AND SIGMOIDOSCOPE

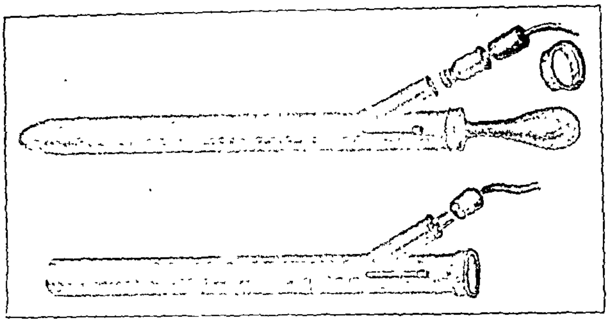
DUDLEY ROBERTS, M.D.
BROOKLYN, N. Y.

Those who have used the various types of proctoscopes and sigmoidoscopes know that each has certain advantages and disadvantages. The instrument known as the Kelly tube, depending on a headlight for illumination, is the simplest and cheapest. With it the upper rectum and sigmoid are often examined with great difficulty. The examiner is forced to assume an exceedingly awkward position in order to line up his eye, the light and the long tube. Instrumentation with this method of illumination is difficult, as the instrument and hands interfere with the light. The light cannot be satisfactorily thrown through the window such as is used to close the proximal end of the tube in effecting distention with air.

The use of tubes which are arranged with a small electric light on the distal end has meant a marked advance in our knowledge of the upper rectum and sigmoid. The chief objection to this method of illumination is the frequency with which the small lamp or its protecting capsule of glass becomes smeared with feces or other discharges. This necessitates the withdrawal of the speculum or the light-carrier and sometimes an annoying delay in the examination. The lumen of the examining tube is encroached on by the light, and its carrier or an accessory tube applied along the outside makes the passage of the speculum more uncomfortable. The tiny electric lights with their especially made bases are easily burned out, causing considerable annoyance and in the long run some expense.



New proctoscope and sigmoidoscope.

A wonderfully satisfactory illumination is secured by the new principle of lighting examining tubes herewith described. As illustrated, a flat-faced metal filament lamp, having the standard miniature base, is snugly held in a tube which projects at an agle of thirty degrees from the main tube. The inside of the main tube is heavily plated and highly polished with lines of polish running lengthwise of the tube. The lamp-holding tube is of exactly the same size in all instruments and the same lamp-carrier serves for any number of instruments. Owing to the manner of polishing no light is thrown back into the eye from the walls of the tube, all the rays going to the distal end. The light is carried brilliantly to and even several inches beyond the end of as long a tube as could possibly be of practical use.

Entrance into the sigmoid is occasionally facilitated by inflation of the bowel or puffing aside obstructing folds of mucous membrane. In this instrument the glass window is made the full size of the lumen of the tube and does not obscure the view in the least. The metal collar which holds the glass screws on to the end of the tube, making a perfectly air-tight joint. To the small offset tube a small hand-bulb is attached when inflation is to be used. These features are necessary or useful in only a comparatively small proportion of cases and are not used on the tubes which are spoken of as proctoscopes.

The end of the obturator is much less blunt than in previously made instruments. Bluntness is not necessary for safety, as it is customary to withdraw the obturator after effecting an entrance through the anus and then to make farther entrance into the rectum by sight. It is ite remarkable how much more easily this olive-shaped urator passes through the anal canal than do the er blunt-ended obturators.

CARDIAC DI

B

EV

The following h
tion, demonstrates

Patient, 19 years old, suffering from cardiac displac
pleurisy.

displaced into the right side and still for ma
perform its function. Indeed, in this case, th
displacement itself seemed to produce little or
comfort. Death was indirectly due to the cardiac
tation, and compensatory failure was not pronou
until late in the case.

History.—The patient, M. S., a girl aged 19, was of Swedish descent, with light complexion, and "scrofulous." The family history was generally good. She weighed over 14 pounds when born, and was healthy and vigorous until 7 years old. At that time she contracted "a severe cold on the lungs," causing shortness of breath. The family physician opened the pleural cavity, from which a large amount of pus was evacuated. For eleven years there was a continuous drain; consent to operation for radical cure was refused by the family. During a period of one year before death, the wound remained closed. Although greatly deformed and retaining the childish type of figure, the patient otherwise developed fully so that, until the great emaciation during her last months had wasted her, the arms and legs were strong, of full size and well proportioned. Mental development was rather above the ordinary; she had passed all the grades in public school up to the third year of high school.

Examination.—The heart was displaced entirely over to the right side of the sternum and filled the whole upper right side of the chest, being crowded up under the clavicle, the apex-beat striking sharply and being visible in the third right interspace, between the middle and outer third. Apparently, there was no lung-tissue above the heart, nor were respiratory sounds audible behind, until the lower part of the scapula was reached. The entire respiratory act seemed to be performed by the lower and middle lobes of the right lung. The left lung had atrophied.

Course of Disease.—Dilatation, though caused partly by the pulmonary obstruction, was also, to no small extent, due to the overexertion incident to school life. The patient lived two miles from school and had to climb a hill to reach it. During winter season the snow drifts were often three feet deep, yet, she scarcely missed a day. During the last winter of her life, the distress caused by swelling of her limbs and breathlessness forced her to abandon her studies. Death resulted from an intercurrent catarrhal pneumonia of probably influenzal origin that terminated in pulmonary edema. No autopsy was procured.

THE ELICITATION OF THE KNEE-JERK

AUGUSTUS A. ESHNER, M.D.
PHILADELPHIA

In addition to common and accepted methods of eliciting the knee-jerk, including that described by Dr. Curran Pope,[1] I have found two procedures useful in this connection. The one consists in supporting the leg to be examined on an inclined plane, while the patient is seated, the inclination being susceptible of variation in accordance with the requirements of the individual case. (Fig. 1.) By this means, relaxation of the lower extremity is secured independently of the volition of the patient, and the limb can be placed in a position most favorable for the development of the reflex. This device is particularly useful in the case of obese individuals and of those persons, old or young, who are either unable or unwilling to cooperate with the examiner, or who oppose or resist his efforts.

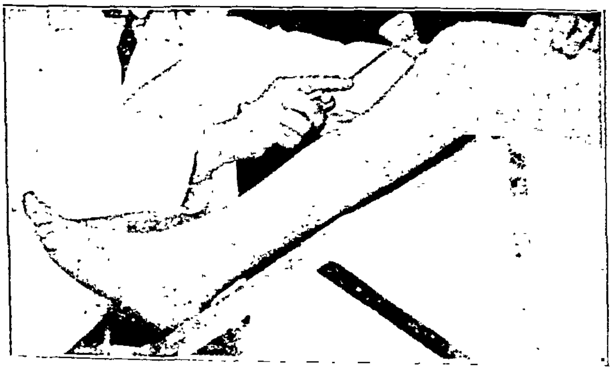

Fig. 1.—Leg supported on inclined plane, while patella tendon is struck with plexor and hand is applied over quadriceps extensor tendon.

The second procedure consists in the application of the palmar surface of the index-finger of one hand over the patellar tendon and striking the dorsal surface of this finger with a percussion-hammer or with the opposite clenched hand. (Fig. 2.) In this way a slight contraction of the tendon can sometimes be felt when it cannot be seen and when the leg is not thrown forward in extension.

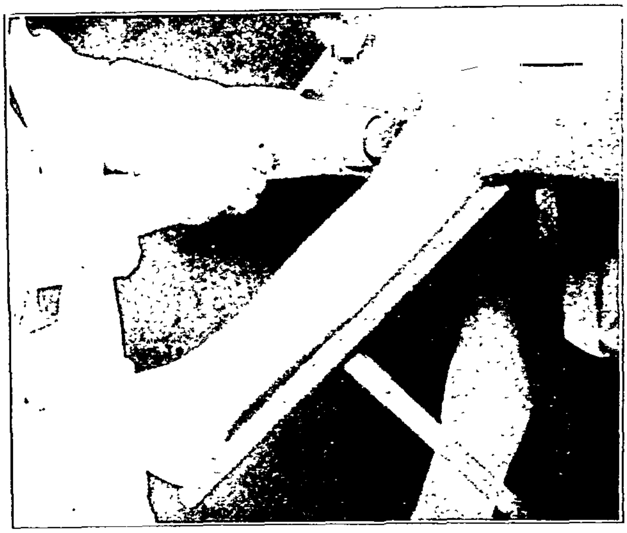

Fig. 2.—Leg supported on inclined plane, with finger applied over patella tendon and to be struck by plexor.

When there is doubt as to the presence of the knee-jerk, it is useful also to apply the palmar aspect of one hand over the quadriceps muscle or its tendon, while the patellar tendon is struck with a plexor or with the ulnar margin of the other hand (Fig. 1).

Under any of the circumstances mentioned, it is best in attempting to elicit the knee-jerk to bare the knee entirely, so that the stimulating blow is applied directly to the cutaneous surface overlying the tendon.

SOME LESSONS DRAWN FROM A SERIES OF TWENTY-EIGHT EXTERNAL OPERATIONS ON FRONTAL SINUS AND ETHMOID LABYRINTH *

HENRY HORN, M.D.
SAN FRANCISCO

Having determined that an external operation on the frontal sinus and ethmoid labyrinth is necessary, there seems to be no question but that the terribly mutilating, truly radical operation of Riedel, with its complete destruction of the supra-orbital ridge, is the one which gives us the greatest certainty of a cure. The resulting deformity is so great that the operation is scarcely ever carried out to-day, but the Killian operation, or some of its modifications, is substituted.

Owing to the manner of polishing no light is thrown back into the eye from the walls of the tube, all the rays going to the distal end. The light is carried brilliantly to and even several inches beyond the end of as long a tube as could possibly be of practical use.

Entrance into the sigmoid is occasionally facilitated by inflation of the bowel or puffing aside obstructing folds of mucous membrane. In this instrument the glass window is made the full size of the lumen of the tube *and does not obscure the view in the least.* The metal collar which holds the glass screws on to the end of the tube, making a perfectly air-tight joint. To the small offset tube a small hand-bulb is attached when inflation is to be used. These features are necessary or useful in only a comparatively small proportion of cases and are not used on the tubes which are spoken of as proctoscopes.

The end of the obturator is much less blunt than in previously made instruments. Bluntness is not necessary for safety, as it is customary to withdraw the obturator after effecting an entrance through the anus and then to make farther entrance into the rectum by sight. It is quite remarkable how much more easily this olive-shaped obturator passes through the anal canal than do the older blunt-ended obturators.

As the illumination of the distal end depends on the polish of the inner wall of the tube it is essential that some care be taken to keep the inside clean and free from tarnish. The easiest and best way of doing this is to force a narrow towel through the lumen, the first part of the towel being moistened with soapy water. The dry part is later pulled back and forth through the tube until a satisfactory polish is reestablished. Although *not absolutely necessary it is well to make it a habit to* clean the inside in this way each time after sterilization.

Three styles of the instrument are made. Two short tubes differing in caliber are designated as the large and small proctoscope. These are simpler than the tube illustrated, having no appliance for inflation. Either of these cheaper forms of instruments will be found satisfactory in the large majority of cases where high examination of the sigmoid is not to be attempted. The third style, designated as the sigmoidoscope, differs from the others in its greater length and parts added for air *dilatation.*

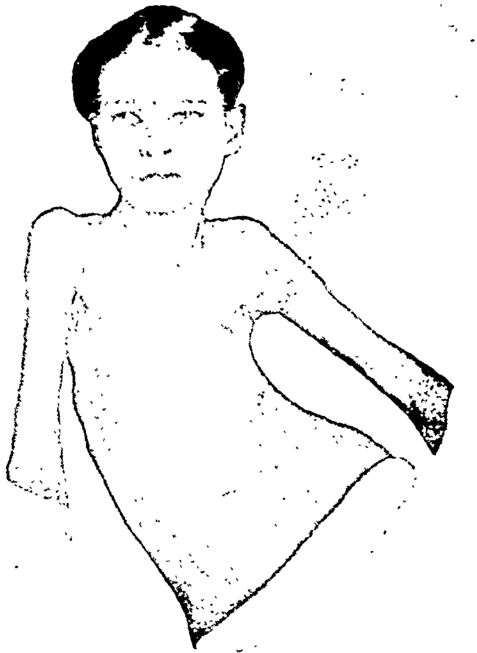
Only practical experience with these instruments could possibly convince one of the remarkable illumination secured and of the ease with which thorough examination and instrumentation can be accomplished in all cases.

84 Remsen Street.

CARDIAC DILATATION AND DISPLACEMENT DUE TO PLEURISY

EVAN O'NEILL KANE, M.D.
KANE, PA.

The following history, with accompanying illustration, *demonstrates how completely the heart can be* displaced into the right side and still for many years perform its function. *Indeed, in this case, the mere* displacement itself seemed to produce little or no discomfort. Death was indirectly due to the cardiac dilatation, and compensatory failure was not pronounced until late in the case.



Patient, 19 years old, suffering from cardiac displacement due to pleurisy.

History.—The patient, M. S., a girl aged 19, was of Swedish descent, with light complexion, and "scrofulous." The family history was generally good. She weighed over 14 pounds when born, and was healthy and vigorous until 7 years old. At that time she contracted "a severe cold on the lungs," causing shortness of breath. The family physician opened the pleural cavity, from which a large amount of pus was evacuated. For eleven years there was a continuous drain; consent to operation for radical cure was refused by the family. During a period of one year before death, the wound remained closed. Although greatly deformed and retaining the childish type of figure, the patient otherwise developed fully so that, until the great emaciation during her last months had wasted her, the arms and legs were strong, of full size and well proportioned. Mental development was rather above the ordinary; she had passed all the grades in public school up to the third year of high school.

Examination.—The heart was displaced entirely over to the right side of the sternum and filled the whole upper right side of the chest, being crowded up under the clavicle, the apex-beat striking sharply and being visible in the third right interspace, between the middle and outer third. Apparently, there was no lung-tissue above the heart, nor were respiratory sounds audible behind, until the lower part of the scapula was reached. The entire respiratory act seemed to be performed by the lower and middle lobes of the right lung. The left lung had atrophied.

Course of Disease.—Dilatation, though caused partly by the pulmonary obstruction, was also, to no small extent, due to the overexertion incident to school life. The patient lived two miles from school and had to climb a hill to reach it. During winter season the snow drifts were often three feet deep, yet, she scarcely missed a day. During the last winter of her life, the distress caused by swelling of her limbs and breathlessness forced her to abandon her studies. Death resulted from an intercurrent catarrhal pneumonia of probably influenzal origin that terminated in pulmonary edema. No autopsy was procured.

THE ELICITATION OF THE KNEE-JERK

AUGUSTUS A. ESHNER, M.D.
PHILADELPHIA

In addition to common and accepted methods of eliciting the knee-jerk, including that described by Dr. Curran Pope,[1] I have found two procedures useful in this connection. The one consists in supporting the leg to be examined on an inclined plane, while the patient is seated, the inclination being susceptible of variation in accordance with the requirements of the individual case. (Fig. 1.) By this means, relaxation of the lower extremity is secured independently of the volition of the patient, and the limb can be placed in a position most favorable for the development of the reflex. This device is particularly useful in the case of obese individuals and of those persons, old or young, who are either unable or unwilling to cooperate with the examiner, or who oppose or resist his efforts.

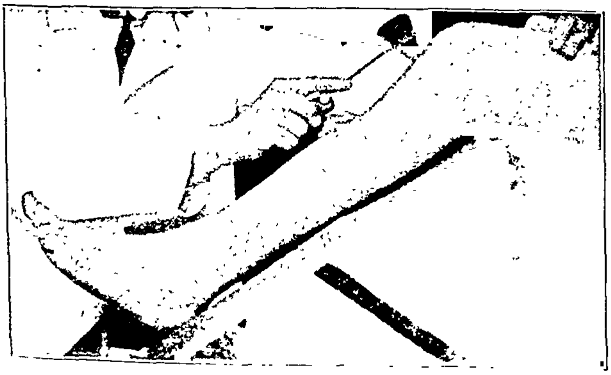


Fig. 1.—Leg supported on inclined plane, while patella tendon is struck with plexor and hand is applied over quadriceps extensor tendon.

The second procedure consists in the application of the palmar surface of the index-finger of one hand over the patellar tendon and striking the dorsal surface of this finger with a percussion-hammer or with the opposite clenched hand. (Fig. 2.) In this way a slight contraction of the tendon can sometimes be felt when it cannot be seen and when the leg is not thrown forward in extension.

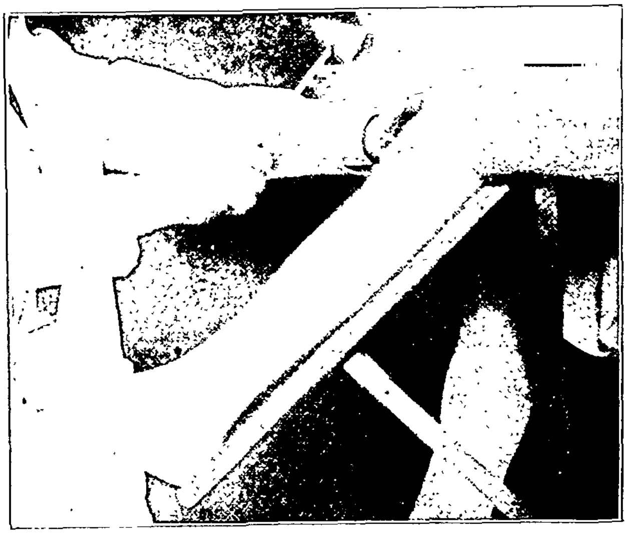

Fig. 2.—Leg supported on inclined plane, with finger applied over patella tendon and to be struck by plexor.

When there is doubt as to the presence of the knee-jerk, it is useful also to apply the palmar aspect of one hand over the quadriceps muscle or its tendon, while the patellar tendon is struck with a plexor or with the ulnar margin of the other hand (Fig. 1).

Under any of the circumstances mentioned, it is best in attempting to elicit the knee-jerk to bare the knee entirely, so that the stimulating blow is applied directly to the cutaneous surface overlying the tendon.

SOME LESSONS DRAWN FROM A SERIES OF TWENTY-EIGHT EXTERNAL OPERATIONS ON FRONTAL SINUS AND ETHMOID LABYRINTH *

HENRY HORN, M.D.
SAN FRANCISCO

Having determined that an external operation on the frontal sinus and ethmoid labyrinth is necessary, there seems to be no question but that the terribly mutilating, truly radical operation of Riedel, with its complete destruction of the supra-orbital ridge, is the one which gives us the greatest certainty of a cure. The resulting deformity is so great that the operation is scarcely ever carried out to-day, but the Killian operation, or some of its modifications, is substituted.

---

[1] Pope: THE JOURNAL A. M. A., June 10, 1911, p. 1705.

* Read in the S[illegible]on on Laryngology, Otology and Rhinology of the American Me[illegible]l Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

In Riedel's operation[1] there are no dead spaces left behind; in Killian's operation,[2] the dead spaces, with their subsequent difficult drainage, constitute that element of doubt which does not allow us always to promise a certain cure. Admitting the necessity of an external operation in any given case, how are we to overcome this intrinsic objection of dead space which is the weak point in an otherwise ideal operation?

In presenting the present series, I do not do so because of the number or the very satisfactory results which have been obtained, but because I think that certain lessons can be derived from this group of cases, and also because I believe I have something to offer, not only in the way of getting quicker and more lasting results, but of limiting the severity and extent of the operation and overcoming the problem of drainage of the dead spaces, which is the weakness of the Killian operation.

The simplest way to classify cases of chronic suppuration of the frontal sinus and ethmoid labyrinth is as follows: First, cases with cerebral or orbital complications which should all be operated on by the external method, and second, the vast majority of patients who come to us with headaches and pus discharge.

Most patients in this last class can, by intranasal methods, either be completely cured or their headaches relieved and the discharge reduced to what I take the liberty of designating a "specialist's minimum"—an amount of discharge which a well-trained rhinologist can control without danger to the patient over a long period of time. With this result the patient may be satisfied, the true surgeon never. I am not altogether certain my coinage of the phrase is a happy one, but I use it in contradistinction to the often-used expression, "safe minimum," meaning thereby that the patient can go on for the rest of his life with such a discharge without danger, an idea which Gerber[3] has shown to be false and dangerous.

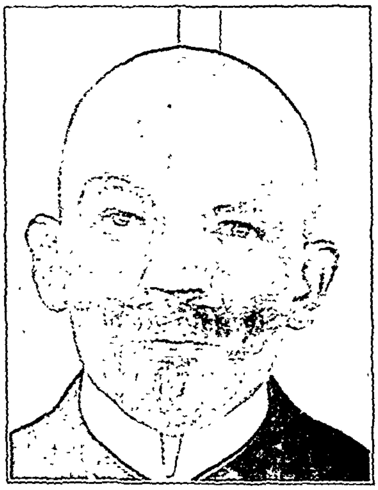

Fig. 1.—Right-sided Killian operation, with very large frontal sinus, necessitating vertical incision to hair line.

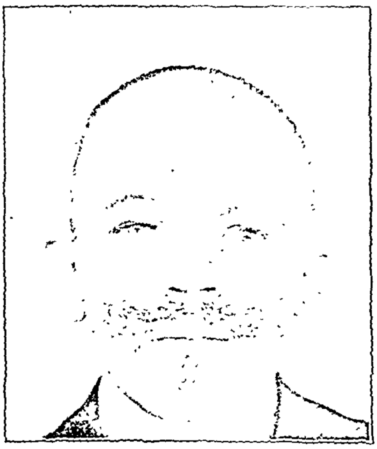

Fig. 2.—Same case as Fig. 1 after injecting large quantities of paraffin

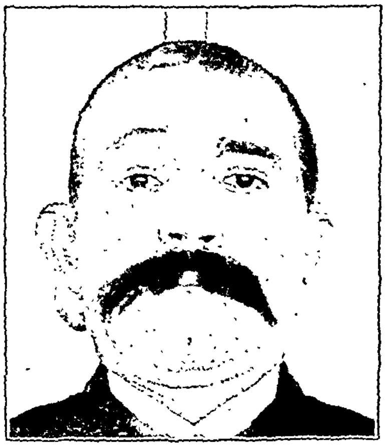

Fig. 3.—Extensive deformity after Killian operation, subsequently entirely filled out with paraffin.

There are many patients who are not in a condition to have constant attention even over a period of a few weeks. There may be considerations of time, finance and geography, that may cause what one might designate the sociologic operative indications to outweigh the clinical indications. The sociologic factor is more to be considered in America than in Europe. There the universal insurance system for workmen allows patients to remain away from work for weeks at a time. They lose nothing by it and their families are provided for. In every large city there are well-equipped special clinics, and the country districts are always within easy reach of the cities. In America, distances are great, insurance is unknown and clinics are scarce. The patient must be cured quickly, safely and radically.

During the last few years, an interesting wave of uncertainty has swept over the minds of European rhinologists in regard to the indication for the Killian operation. Since Gerber's book[3] appeared in the fall of 1908, reporting thirty-six postoperative deaths, there have been added not less than ten cases of the same kind.

This new chapter of postoperative, fatally terminating complications is the basis of this uncertainty, and that master of rhinologic technic, Hajek, has given the matter much serious study. His two recent fatal consecutive cases have altered his viewpoint of a few years ago. They occurred in cases in which no danger-signal appeared previous to the operation; they came at a period of his career when his operative experience was ripe, and nothing was neglected in the way of technic. Six days after the operation the first patient died of an *intradural abscess*; the second patient on the third day of a septic meningitis.

A study of such cases, so conscientiously reported, is the only means which give us a basis for improving our technical skill or reducing the mortality. The autopsies have impressed on us the one pregnant point—that the complications had their origin, not in the operated area, but in some overlooked ethmoid cell, some other neglected accessory cavity, especially in some area of pus which *had not been drained away*, and which had given rise to an area of infection.

These bitter experiences teach us not to neglect any possible method of determining the condition of the accessory cavities before the operation, and that perfect and constant drainage after the operation is the only protection which to my mind has been developed in recent years. These two prime requisites can be fulfilled by measured negative pressure alone.

---

[2] Killian: Arch. f. Laryngol., 1902, xiii.

[3] Gerber: Die Komplicationen der Stirnhöhlenentzündungen, S. Karger, Berlin, 1909.

Although originally designed as an aid in the after-treatment,[4] I have come to regard measured negative pressure as the most important accessory aid in the clinical diagnosis of accessory cavity disease, followed in the order of their importance by the *x*-ray and transillumination. By means of my differential method[5] with tampons and aristol combined with gradually increasing measured pressure,[6] one can exclude every cavity but the one under consideration; can determine whether the ethmoid cells are involved alone or in conjunction with the frontal; can tell whether the frontal alone is involved, whether the diagnostic washing out of the frontal sinus actually took place or whether an anterior frontal cell was entered; can differentiate between pus in the frontal sinus or a pus process grafted on a catarrhal process. These points can all be determined previous to the operation and give us a great increase in security.

The greatest protection which we have against a fatal termination, and the greatest security for an absolute cure, is the preliminary intranasal work, which, if possible, should extend over months. All ethmoid cells, as far as it is possible to reach them from the nose, should be cleaned out. The diseased sphenoid and the antrum should be opened and if possible cured. The second and equally important requirement is that the operation should be carried out as radically as possible, so that no fragment of diseased mucous membrane, no single ethmoid cell shall remain behind. This proposition I urged three years ago,[7] and was based on the fact that I had had no mortality and that my results were unusually good. I only too clearly recognize the fact that my experience has been limited, and although since then I have not changed my method or ideas, I am directly at variance with Hajek, who, as I said, influenced by his two unfortunate cases, now urges that the mucoperiosteal lining of the roof of the ethmoid labyrinth be allowed to remain, *even at the cost of the thoroughness of the operation.*

Hajek[8] even asserts that such an incomplete operation will have no influence on the final outcome of the case, or at any rate will not disturb the patient as long as sufficient drainage is afforded. With this view I cannot agree, and in three of my cases in which I was forced to reoperate, the findings were proof positive that ultimate recovery would have been impossible.

The very reasons which Hajek gives for considering this retention of pyogenic mucous membrane a protection would, if we can believe the findings of my autopsies *in vivo,* in all probability have led to future severe trouble. In fact, Gerber[3] has proved that many cases of uncomplicated frontal sinus disease have, as a result of a Killian operation, finally terminated fatally, and this to my mind because of the incompleteness of the operation.

Hajek draws his conclusions from a series of about forty cases, while my experience is based on about thirty. He holds with Gerber[3] that a large number of the fatal cases have their origin in an injury or a complete exposure of the roof of the ethmoid labyrinth and the lamina cribrosa. I do not believe in the protecting power of this diseased mucoperiosteal lining of the roof of the ethmoid labyrinth, which is supposed to act as a protection against intracranial complications, but that we must place our reliance from the very first on perfect drainage. Such drainage is only possible after the removal of the gauze at the end of forty-eight hours, by the use of negative pressure.

I maintain that in my twenty-eight cases in which a cure took place, in seven of them in from five to eight days after the operation, in twelve cases from ten to fourteen days after the operation, and in three cases in less than three weeks after the operation, the results could only be obtained, first and foremost, by the most radical and exact operation, and second, by the use of negative pressure during the after treatment to secure perfect drainage.

In those of my patients who were not absolutely cured, and on whom I reoperated, overlooked ethmoid cells were always at the bottom of the trouble, and the sad lesson was always forced on me that every time my lack of boldness or of a retention of too much of the processus frontalis, a miser's greed in sparing the mucous membrane of the nose, or a timidity in attacking the tiny cells deep down on the roof of the ethmoid labyrinth, resulted in a temporary failure.

In any case in which after operation the mucous membrane is seemingly dry, and even after repeated inspection carried out over a number of days shows a drop of pus by suction, the cure is not complete, but some vagrant ethmoid cell has been left behind which is the cause of the trouble and may necessitate months of expensive and nerve-racking treatment.

In one double-sided operation, in which the patient had complained for years of violent right-sided frontal headaches, a curious phenomenon was observed, the only thing of the kind I have ever had the opportunity of noticing. In making a preliminary examination by suction, it was noted that the physiologic limit for negative pressure was lower on the right side than the left.

The physiologic limit is a term I have used to designate the height of pressure which each patient can bear with comfort, or a point at which bleeding begins to take place from the mucous membrane of the nose. Although the physiologic limit for bleeding may vary with the two sides of the nose, depending on the pathologic conditions present, the limit for discomfort has always been about the same for the two sides. In this case, however, the patient complained of much pain coming on with 6 cm. less pressure on the right side than on the left.[9] As the patient expressed it, she felt as if her brain was being "drawn out." At the operation the angle between the floor and the roof of the ethmoid labyrinth was unusually narrow, perhaps 80 per cent. smaller than in the ordinary case. In removing the cells, a dehiscence of the roof was noted about 0.5 by 1 cm., through which the dura showed clear and glistening. There was no pulsation and it was difficult to make out at first whether I was dealing with dura or not. In spite of Hajek's warning, however, the roof was thoroughly cleaned off. Whether this dehiscence was operative, as some of the visitors present maintained, or whether it was preoperative, I could not determine. During the after-treatment, however, the same phenomenon was always observed; the right side was 5 to 6 cm. more sensitive than the left. After about six weeks the sensitiveness entirely disappeared.

This case teaches us two things: First, in all probability the dura on the roof of the ethmoid labyrinth is no more sensitive to infection than the dura on the roof of the tegmen tympani. Who would think of leaving a fragment of diseased mucous membrane in a radical mastoid operation because the tegmen was paper-thin? The dura is exposed in a large percentage of such cases and cerebral complications rarely follow. Second, this lowering of the physiologic limit for discomfort on the diseased side may lead to a method whereby we may suspect, preoperatively, a dehiscence of the bony wall.

[9] The apparatus for determining negative pressure is fully described by me in the Ann. of Otol., March, 1910, and can be obtained from V. Mueller & Co., Chicago.

Before concluding, there are a number of minor points to which I wish to draw attention in passing, although I have nothing original to add in the matter.

The uselessness of the retention of a nasal mucous membrane flap has long ago been decided on. If I am not mistaken, Killian himself has given it up.[10] In my series I never attempted but twice to carry out this procedure and before the operation was completed I saw that during the subsequent dressings the flap would be apt to come loose and therefore snipped it off. I do however believe and my contention is borne out by at least one European observer, that the use of the negative pressure in the after-treatment seems to have a tendency to inhibit the formation of granulations around the drainage openings. At least I have never yet had to snare or burn away any exuberant granulations in my cases.

The question of the necessity of a primary suture of the external wounds is still an open one.[11] The more conservative operators, Hajek and Killian, contend that even when no intracranial complications are present, but when the pus is unusually foul and dangerous-looking, a secondary suture would be the safest plan. In all of my cases the wounds were closed with a primary suture with the exception of one in which I experimentally did a secondary suture. The cosmetic result was good, but not the perfect result that in the ordinary case I now consider a *sine qua non*. In the case already mentioned with the dehiscence, I did, with some misgivings, a primary suture, but I considered my drainage absolute, and the necessity of a perfect cosmetic result must be considered in the case of a young woman.

In my first few cases I took great pains to spare the attachment of the trochlearis.[12] Now I pay no attention to the matter and in my series had but one temporary diplopia which lasted less than a month. There are often series of small ethmoid cells which extend down almost to the foramen of the optic nerve and which are concealed unless a very free dissection of the orbital contents is made by first loosening the attachment of the trochlearis. In one of my reoperated patients, when I had taken the greatest pains to do a very radical operation, a feeling of pain behind the eye combined with the appearance of a few drops of yellow pus, shown only by suction, led to the discovery at the second operation of a single row of six to eight ethmoid cells filled with small polypoid masses, almost surrounding the upper half of the edge of the optic foramen.

In but two of my cases did I find it necessary to use paraffin to overcome the sinking of the supraorbital space. The frontal sinuses in both cases, as you can see by the illustrations, were exceedingly extensive and deep, extending almost to the hair line. In one, a perpendicular incision was necessary to thoroughly eradicate all the dead space. Very extensive paraffin injections brought about most satisfactory results.

In conclusion I wish to emphasize the fact that I look on the Killian operation as a very serious procedure; that the indications for its performance are narrowing instead of broadening; that it should never be undertaken without a thorough preliminary intranasal preparation carried out for weeks or even months before the operation; that if possible the diseased sphenoid and antrum should be previously healed.

My present operative indications are distinctly distasteful to my operative inclinations. Intracranial complications should of course all be operated by the external route. If in the other class, in which headaches and pus are the dominant factors, we cannot heal the lesion by intranasal methods, and if there are no sociologic contra-indications, we can allow the patient to stay under observation with a discharging sinus and some slight headaches.

THE VARIOUS PATHOLOGIC CONDITIONS INVOLVING THE FRONTAL SINUS *

B. R. SHURLY, M.D.
DETROIT

Nature has provided a most elaborate series of air-spaces in her construction of the bony labyrinths of the head. This plan of animal engineering is a structural necessity in vertebrates of aerial locomotion (birds). It is a design of great comfort and utility to the more developed species that assume the more erect posture.

The frontal sinuses may be classified as a part of this general plan of human machinery that demand the qualities of lightness in the construction of the head with a maximum of protection to the skull-case with the properties of resonance and lubrication to the upper air-passages. The structural units of the body are marvelous in their response to the laws of use and disuse or supply and demand, and we find that the frontal sinuses develop and enlarge extensively at puberty. As the subject of this paper is diseased states of the frontal sinuses, it is unnecessary to dwell at length on details of anatomy, yet it should not be forgotten that certain unusual structural findings exert their anatomic influence on the pathology.

Cryer has pointed out to this Section many interesting conditions relating to the abnormal morphology of the frontal sinuses. The absence of sinuses, the presence of septa, wide variations in contour and dimensions, absence of bony walls, presence of ethmoid cells within the sinus, variations in thickness of the structural bone and anomalies of the frontonasal duct may be mentioned as a few of the anatomic discoveries that may influence the pathologic conditions, the surgical indications and therapy in this region.

The physiologic phenomena of the nasal passages are in close relationship to many pathologic conditions in the frontal sinuses. Hyperemia, intumescence, and hypertrophy of the mucosa and turbinates are frequent attendants or etiologic factors of sinus disease.

To discuss the problems of pathologic conditions involving the frontal sinus comprehensively it is necessary to establish several distinct classifications. We find immediately on investigation that the frontal sinus (as we should expect) shares with the other accessory cavities in a number of pathologic processes that are common to all.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

It is only within the present century that frontal sinus disease has been recognized and operated on externally. In 1839, Dezeimeris, in 1859, Bonyer, and in 1872, Steiner contributed work of important pathologic value to this subject. It remained for Zuckerkandl to publish the most exhaustive and unequaled treatise on the accessory sinuses.

Disease of the frontal sinus may be grouped into six subclassifications: (1) acute catarrhal or suppurative; (2) chronic catarrhal or suppurative inflammation; (3) confined suppuration; (4) infectious conditions, as tuberculosis and syphilis; (5) mucocele; and (6) tumors, foreign bodies.

The pathologic processes that invade the frontal sinuses are those peculiar to mucous membranes in general and to the other accessory sinuses in particular. The problems of pathology in the region under consideration are modified by the anatomic confines of the bony walls and a small ostium for drainage or infection. Undoubtedly the most frequent pathologic condition of our north temperate zone involving the frontal sinus is the secondary catarrhal inflammation attending acute coryza. The process is usually one of extension. The sinus is protected from infection by its secretion falling through a comparatively long dependent canal. The acute inflammatory processes are frequently nothing more than a renewed bacteriologic activity of some old slumbering infection.

While unusual types of micro-organisms invade this frontal recess, the staphylococcus, streptococcus, pneumococcus and the influenza bacillus, are by far the most frequent invaders. The problems of inflammation within bony cavities, lined with mucous membrane, have much in common with like problems of inflammation elsewhere. The necessity for drainage is more important and requires alertness in diagnosis, with prompt attention to the surgical principles of drainage. Again, there are pathologic problems of the frontal sinus that closely simulate those of the mastoid region. In some cases acute frontal sinus abscess has broken down the bony walls, and even the anterior wall, within three days and this possibility must be borne in mind. Inflammation with hemorrhage and a closed nasal duct may develop especial pathologic conditions. The bloodclot may shrink and undergo fermentation. The activities of the gas-producing microorganism in turn may develop a sharp negative pressure similar to the middle-ear and mastoid phenomena. With this pathologic state, the aggravated symptoms of frontal pain or supra-orbital neuraligia may be developed, which pain or neuralgia is relieved by spontaneous or artificial drainage.

With these acute processes of inflammation may be associated pin-head or larger areas of necrosed bone attended by symptoms of pain. These are exceedingly difficult of diagnosis and have yielded to discovery through the findings of the *x*-ray. Given the fact of acute infection of the frontal sinus with the various types of microorganisms, the problems of pathology in general and inflammation in particular are decidedly influenced by several unknown factors, which we must endeavor to investigate in our cases. X may represent the unknown microbe; y may represent its virulence; z may represent the opsonic index of the individual host. These unknown factors of our algebraic problem may be determined approximately. The variety and virulence of the microbe, the resistance of the patient and the question of drainage, determine the extent, the character, the type, and the various phenomena of acute inflammation in this region; and we understand the pathology of the individual case, the more nearly we appreciate the life-history and habits of the infecting microbe.

The influence of the biochemistry of the blood and lymph and the general systemic condition of the patient must be constantly borne in mind. It is impossible to separate any special pathology of the frontal region from pathology in general. Suppurative and catarrhal conditions are closely related to systemic conditions such as the examthematous diseases of children.

In frontal suppuration it should be a routine procedure to obtain a culture and study the bacteriology on account of the valuable information that may be obtained in relation to the etiology, pathology, prognosis and treatment. It is not only difficult, but frequently impossible to draw the dividing line between acute, subacute, and chronic processes in this region. When the transition occurs, it is characterized by the growth of connective tissue. This may be attended by hypertrophy—general, local or scattered. It may be followed by cyst formation or polypi, or the development of osteomata. The infiltration stage with thickening of the mucosa may go on for months characterized by a mucous or seropurulent discharge with little discomfort to the patient.

The formation of cysts and polypi are quite frequent in the other accessory sinuses—especially the ethmoidal cells and antrum. Retention cysts arise many times as the result of contracting connective tissue thrown into the mucosa and choking the ducts of the mucous glands. Polypi are less common. When the chronic inflammatory processes continue and extend deeply involving the periosteum, and depositing inorganic salts in a meshwork of new cells and capillaries, we may have bony infiltration and the development of osteomata.

Chronic suppuration may be free or confined, depending on the patency of the ostium frontale. A macroscopic examination of the sinus reveals a thickened rough, soggy pyogenic lining membrane which is bathed with yellow and at times fetid pus. It is unusual to find the same pathologic picture associated with the anterior ethmoid cells or antrum. Suppuration may follow trauma.

Fistulas indicate necrosed sinus wall and occur most frequently at the upper internal angle of the orbit. The perforation is usually in the inferior wall of the sinus. When the anterior wall is perforated the point of selection is along the superciliary ridge. Eye clinics at Berlin report one fistula in 18,000, while in Vienna one fistula in 9,000 was found.

Among the more frequent infectious conditions that involve the frontal sinus may be mentioned influenza, tuberculosis, and syphilis. The former variety (influenza) is seen after the acute ravages of the winter grip epidemic have passed. The waves of acute infection subside, leaving colonies of activity in any or all of the accessory cavities. The frontal is frequently the cavity of selection.

Post-mortem examination in subjects who have died of tuberculosis has revealed the presence of tubercle bacilli in normal sinuses. The presence of this disease is rarely primary and shows the pathologic phenomena of tuberculosis of mucous membranes by extension. As nasal tuberculosis is rare, frontal sinus tuberculosis is exceedingly unusual and when present, exhibits no peculiar characteristics. The manifestations of syphilis are usually secondary to ulceration in neighboring tissues. An obscure form may be necrosis of the anterior wall. This condition came under my observation recently—a diagnosis could be made with the x-ray only, as all other methods failed to give any information whatever. Syphilitic processes in this region are deep-seated and invade the soft parts and bone with extensive destruction in the presence of mixed infection. Many of them are not benefited by ordinary antisyphilitic treatment.

Although sinus affections are quite common with general systemic infections, the frontal is less frequently involved than the other accessory cavities. In diphtheria the Klebs-Löffler bacillus may be found, and it may be infected with erysipelas, typhoid fever, variola, pneumonia, or cerebrospinal meningitis.

In addition to inflammatory and suppurative conditions, new growths may appear. Primary benign or malignant tumors, as fibroma, sarcoma, or carcinoma, are exceedingly rare. They involve this region as secondary growths by extension without any unusual change in their pathology. Epithelioma and sarcoma are the most frequent tumor formations involving the frontal sinus. A few cases of mucocele and pneumatocele are on record. Helly has reported nine of the latter. Farlow's case of mucocele with the characteristic "egg-shell crackle" illustrates the pathologic peculiarities of this condition. This tumor appears at the upper and inner angle of the orbital fossæ with a hard surface, slight bony irregularities and develops slowly.

The presence of foreign bodies in the frontal sinus is extremely rare. They occur, however, in both animate and inanimate varieties. A number of interesting cases due to maggots, larvæ and various worms and insects are reported. Bullets, shot, pieces of drainage-tube, broken instruments, constitute some of the inanimate objects recovered. The irritation of foreign bodies is usually followed by marked suppuration.

Modern research has not elaborated any recent remarkable discovery in the pathology of this region. It is necessary, however, that the therapy connected with the frontal sinus should be based on broad and just pathologic foundations. When we appreciate in full measure the value of its teachings the surgery of this region will be placed on the conservative basis where it belongs. The teachings of the ultraradical will be relegated to the realm of oblivion or the mountain of ancient surgical remains. The frontal sinus then, will be opened externally when it is absolutely and pathologically necessary.

If we are to be instrumental in relieving pathologic conditions of inflammatory type in the frontal sinus, this relief must not come through the efforts of surgery alone, but under the prophylactic guardianship of a method of treatment that will prevent and abort acute inflammation and the frequent common "head cold."

32 West Adams Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. SHURLY AND HORN

Dr. E. C. Sewall, San Francisco: My experience with Killian's operation has been limited to twelve cases, and my results have been largely similar to those of Dr. Horn. In my cases, in the beginning, I was somewhat disappointed in the after-results, as regards complete cessation of all secretion, largely due to the lack of proper drainage. This was true even when I felt at the time of operation that I had been particularly careful to get good drainage. Doing a Killian operation, to me, has always been like a stroke at golf: I always feel that if I had another chance at it I could do better. I feel that the operation is surgically correct. I congratulate Dr. Horn on his results. I am certainly very much interested in the use of suction, which in his cases prevented the formation of granulation tissue, which in my cases gave considerable trouble. In this connection I wish to call attention to a suction apparatus which I have introduced into surgery and which I have found of value in this work. I hope to show this apparatus to the Section. Dr. Horn speaks of fatalities being largely due to portions of pus not evacuated. Killian, during my four months with him, five years ago, had a death from osteomyelitis and seemed to look on this as a serious possibility in these cases. When I called again on him a few months ago, I found he was not closing nearly as many cases primarily as before. In my cases, perhaps I have operated too radically, in that I did not do the preliminary work Dr. Horn advocates. And I do not know that I agree with Dr. Horn in submitting the patient to tedious intranasal work on the ethmoid and sphenoid when one has concluded that the Killian operation is necessary. I have included the maxillary antrum in the operation. That may be too radical and in the future possibly I may retract from that position. But I have operated on both frontals, the ethmoids, the sphenoid and the maxillaries at the same sitting and have secured satisfactory results.

Dr. H. B. Graham, San Francisco: I want to congratulate Dr. Horn on the conservatism shown in his paper. I think the radicalism advocated by Jansen of Berlin is certainly not advocated by the majority of rhinologists in Europe to-day. I had the privilege of seeing many European operators work, and at the Budapest conference the tone was conservatism. Hajek and Killian are particularly conservative and I think the men most skilled in intranasal surgery will try every other method before they do a Killian operation. A great deal can be done by intranasal treatment and drainage. The introduction of suction has added a great aid to our drainage methods. The idea that bone dehiscences constitute an indication for the Killian operation is not true to-day. I have had one case in my own practice in which I had been treating the patient four or five months and who was gradually getting better under suction and drainage after operation on the ethmoids. One day I found my washings coming through on the opposite side and I thought I would have to do a Killian operation. But I kept on with the conservative treatment and the patient is now apparently well and has been so for four months. In Vienna I saw a great many patients who had been reoperated on, I am sorry to say, and I think in all there was a lack of technic in the primary operation. The assistants in the clinic were perfectly frank to acknowledge that portions of the mucous membrane had been overlooked.

In the conservative treatment we have a means that has not been mentioned here and that is the use of autogenous vaccination. We have observed at least one case in the Cooper clinic where we used the autogenous vaccine and reduced the infection from a polybacillary to a monobacillary infection. The patient is not cured. What will be the ultimate outcome I do not know, but I think it is of value to know that we can reduce the number of varieties of bacteria in these cases. If we can change a polybacterial pus to a monobacterial one there will be less danger of meningitis in the Killian operation.

Dr. C. F. Welty, San Francisco: When some of the large clinics report that they have ceased to do the Killian operation and a man says he has cured twenty-five consecutive patients, it starts us to thinking there is something wrong somewhere. I am inclined to believe that Dr. Horn's statements are correct, not because of the suction apparatus, but because of a more thorough operation than is usually done. The reason that the Killian operation is in disfavor to-day is because a large majority of the patients are not cured after that operation. If we adhere to the indications as established by Hajek and Killian at the last international congress, we are certainly not going to go ahead. The indications they gave then were threatening cerebral symptoms. It is self-evident that all such patients have to be operated on, regardless of whether they will recover entirely or not. I have operated on patients, with and without the use of Dr. Horn's suction apparatus, and they got well in three or four weeks. I have operated on other patients since and they have not done so well after a number of months. In the patients that do not get well I feel that the operation has not been sufficiently complete. I cannot believe that the suction apparatus can produce healing if you leave diseased tissue.

DR. SHERMAN VOORHEES, Elmira, N. Y.: Dr. Shurly spoke of a mucocele occurring in these cases and extending into the orbit, destroying the orbital wall. I have had two cases in which the eye-ball was displaced by mucocele and the thrush fungus was found in great numbers. Both patients were operated on by the Killian operation and recovered. Often we will find a deviated septum that should be corrected before the Killian operation is done. I have used for some time the suction apparatus, following the Killian operation and also the intranasal operation, and I can say with Dr. Horn that I think it is of very great use. Sometimes we defer for a long time operation by the Killian method. That is according to the case, to a great extent. I have had two cases in which perforation into the orbit took place following an acute infection of the sinus. In such a virulent case I think none of us would hesitate to operate early. Dr. Horn has emphasized the importance of getting good drainage. We should remember that the outer end of the sinus is lower than the curve in the orbital wall, so that it is necessary to take out the floor of the sinus clear across in order to secure good drainage. I have known some cases in which that was overlooked and the patients came to a second operation.

DR. J. F. BARNHILL, Indianapolis: There is a tendency to get away from radical work, but I think that tendency can be carried too far. There are patients who can be cured by intranasal treatment. On the other hand, no one will doubt that there are patients whom nobody will cure by any method of treatment. These cases are, as a rule, major surgical ones. Sometimes nothing short of applying all of the best surgical principles will effect a cure, and when we learn that this is true and apply such means, we will cure most of them, but there will still be some patients who will not be cured. Dr. Voorhees spoke of one such class of cases. Those of you who have had much of this work, know there are cases such as Dr. Voorhees referred to, in which you cannot overcome the dead spaces and get good drainage unless you have the patient stand on his head a good deal of the time. In such instances, Dr. Horn's suction apparatus may do some good, but I do not think that he believes it will cure all of them. A few patients will permit us to treat them a year or for years and then do radical work. If we do radical work, we must make it what it says it is, radical, and do it so that the operated field can be inspected afterward. We all know the freaks that occur in bone granulation. These often are strange. Sometimes even over night there may form granulations sufficient to hinder drainage and healing of the wound. One of the gentlemen has spoken of a patient who recovered in four weeks after operation. That seems to me almost incredible. I think he means that there was no discharge at the end of that time. He does not tell us what happened the next month or year, when there was perhaps an epidemic of influenza. The fact that a few of these patients die, should not hinder us from going on and doing our duty, any more than the death of a few patients in gynecology should hinder the gynecologists from doing good surgical work, for good drainage secured through careful surgical means is far less dangerous than no drainage. We should treat all patients so as actually to get good drainage. The laity and many practitioners do not recognize the difficulties with which we must contend in this work. To-day probably no work is more difficult than good sinus surgery.

DR. W. R. MURRAY, Minneapolis: I want to emphasize the value of the first paper. It is absolutely essential that we recognize the pathologic conditions that may exist in the frontal sinus before determining our line of treatment. I believe it is the experience of all of us that the indications for the Killian operation are considered less frequent to-day than a few years ago. Often conservative intranasal surgery will give relief in cases of chronic frontal sinusitis. However, the radical external operation has a very distinct place in surgery, and when the indications for such radical operation are present then I believe the Killian operation should be done and not a semi-radical operation. I agree with Dr. Horn that intranasal work should be exhausted before resorting to the external operation, and that intranasal treatment or operation should, if possible, precede the radical operation Unfortunately we cannot always keep the patient under observation and treatment sufficiently long to do this, especially in the case of out-of-town patients.

If I understood Dr. Horn correctly, he attributed the fatal cases he referred to to the presence of over-looked foci of infection in the frontal sinus or ethmoid cells. I should have some doubt as to whether that was the only explanation for the intracranial involvement. In these chronic empyemas the virulency of the microorganisms is usually low and following operation they may become much more virulent. This increased virulency, in connection with some existing pathway of infection, either physiologic or pathologic, which might be present between the sinuses and adjoining cavities, might explain the fatal results. That such communications do exist has been shown by numerous investigators, especially by Zuckerkandl and more recently by Onodi. Of course this is only a possibility and I do not know how we can determine when such conditions are present.

DR. FRANK L. DENNIS, Colorado Springs: For several years we nose and throat men have been using vaccines in sinus and ear affections. Recently, at Dr. G. B. Webb's suggestion, I have introduced the vaccine directly into the mucous membrane of the nose, the idea being that if we can, in the infection of any tissue, put the vaccine into tissue of the same embryologic origin, we may get better and quicker results. Unfortunately, I have not done sufficient of this work to come to a definite conclusion as to its value. However, I feel convinced that I am getting better results from the use of vaccine in this way than before by giving the vaccine subcutaneously.

DR. VICTOR F. LUCCHETTI, San Francisco: I think first of all, the intranasal methods should be exhausted before we proceed to radical work. After the middle turbinal is removed, I believe in many cases fluorescene is of value in washing out the sinus, giving an idea as to the condition of the sinus and also helps to effect a cure. Hydraulic suction is useful, with the use of the masseur of the Victor pump. No one has said anything about the Wassermann reaction. I recently treated a young lady with a bad sinusitis and an ill-smelling discharge, in whom the Wassermann reaction was positive, and she has recovered under the mixed treatment. I have used autogenous vaccine treatment in a number of cases, with benefit, but without a cure.

DR. J. R. FLETCHER, Chicago: Dr. Brem, of the Colon Hospital, Panama, informed me that in 300 autopsies on meningitis cases, some or all of the sinuses were the primary point of the pneumococcus infection. I think we should remember this, because it is not in the literature. The infection almost always extended through the blood-current to the meninges. In a few cases it extended through the ear.

DR. WILLIAM ELLERY BRIGGS, Sacramento, Cal.: Surgery of the nasal accessory sinuses is in its infancy. As a rule it has been far from radical. In fact, many of us avoid radical surgery in these cases until it can be postponed no longer. The results of radical work in this field have not been uniformly good enough to warrant those with little experience to undertake the radical operation on patients who can be made comfortable by less severe means. Those who have not large opportunities for experience would do best to send those patients who need extensive operations to some one who has had abundant chance to see this line of work.

I have seen Dr. Jansen of Berlin do a great deal of radical sinus surgery and he does this work more radically than any other operator that I know. I have seen him operate on the eight sinuses at one time. His flap operation for the frontal sinus is difficult but complete. Whether this will be the ultimate method of operating one can only guess. If such extensive operations are best it will be best to have fewer men doing them. Possibly the autogenous vaccines will accomplish what they have done in other fields of usefulness. If experience should demonstrate this hope to be a fact the radical operation may be rarely needed in the near future.

Dr. B. R. Shurly, Detroit: It is most important that we should give close attention to the acute suppurative processes in the nose. It is these processes that make the trouble later on. It is exceedingly important that every acute inflammation in the nose have as thorough treatment as possible. We must appreciate the difference between the staphylococcus, the streptococcus and the pneumococcus infections; and the difference between the various epidemics and in the virulence of the various strains of microorganisms, especially when the infections invade the accessory nasal sinuses.

Dr. Henry Horn, San Francisco: Dr. Sewall, in his discussion, brought out some points, which I could not cover in my paper because of lack of time. When I said the danger was in the cavities not well drained, I did not refer to osteomyelitic cases. Those have nothing to do with the operation, the infection seems to come as lightning out of a clear sky and kill your patient. The question whether to close the wound primarily or secondarily, depends largely on the personal equation. As to operating without preliminary treatment, of course, if it is not possible to treat patients, and unfortunately here in America that is often true, we may have to eliminate the preliminary treatment. The doctor said he had difficulty with the granulations around the intranasal drainage wound. That is one reason why the preliminary intranasal work is so necessary. Intranasal work should be continued for months, if possible, before the external operation. This allows the epithelial cells to get a start in the region of the future drainage opening and possibly explains why my results were so good and healing was so rapid. When I said a few of them were healed in seven or eight days after the operation, I know that seems an anatomic impossibility, but it is a practical possibility. In seven days after operation in some cases pus cannot be sucked out of the sinuses, and if that condition continues a year or so one is justified in considering the patient healed. What the condition is inside we do not know; that is a pathologic problem on which I am working now. What I have found is that in some reoperative cases the frontal cavity is shut off by connective tissue from the postorbital space and has no communication with the latter. I think probably in some cases the whole cavity is filled up with organized connective tissue. Dr. Sewall spoke of his apparatus. There are dozens of suction apparatus on the market. I only spoke of measured negative pressure, which was first introduced by me into rhinology, and the report published in Germany a few years ago. It is simply measuring the dose. You cannot have any appreciation of the dose of negative pressure unless you measure it with a manometer of some sort. Suction alone will never cure a chronic condition. That is out of the question.

EFFECT OF TUBERCLE PRODUCTS ON EPITHELIUM *

SAMUEL G. DIXON, M.D., LL.D., ALLEN J. SMITH, M.D., LL.D.
AND
HERBERT FOX, M.D.
PHILADELPHIA

That tubercle bacilli or their products have a stimulating effect on epithelial structures we have convinced ourselves. This was quite clearly shown in our work during 1909 and the experiments early in 1910 abundantly corroborated it. We could only be sure of the effects on the epithelium in bile-ducts and bronchi, however, while in mamma and skin epithelium the appearances were far from regular. The work has therefore turned toward establishing conditions which could produce definite continuing results. The results in regard to the organs used are given here.

I. RABBIT EAR

For the purpose of stimulating the growth of epithelium on the ear, two methods were used, one of injecting the material as closely beneath the epidermis as possible, another by rubbing wax derived from tubercle bacilli into an abraded surface on the ear skin. The results seen under the microscope are detailed below.

Ear of Rabbit 57.—Thirteen injections 0.2 mg. dead tubercle bacillus under the skin of ear. Epithelium is essentially the same in the two ears where there are no hair follicles; where hair follicles are present, the epithelium seems a little thicker, but there is no evidence of active multiplication. Very few mitoses can be found; the connective tissue immediately below the epithelium is slightly more cellular in the treated than the untreated ear.

Ear of Rabbit 61.—Fourteen injections 0.5 mg. tubercle bacillus wax under skin of ear. Treated ear: There are many irregularities in the surface epithelium, both in the thickness and in its penetration; there does not seem to be any increase in hair follicle epithelium; connective tissue is rich, well organized and acellular with the exception of one or two minor round-cell collections in vicinity of blood-vessels.

Rabbit 62.—Crude wax molten by gentle heat and rubbed twenty-seven times in six months on an abraded surface on the ear. The other ear was abraded in a similar manner by the same instrument but no wax was applied. After removing a piece of the skin of each ear, the microscopic examination revealed nothing abnormal about the abraded untreated ear skin. The only noteworthy change in the treated ear skin was in the great number of glands and hair follicles throwing off dry epidermal plates, and the collections of crust of dried plates on the surface are certainly thicker than in the control animal.

II. GUINEA-PIG'S MAMMA AND RABBIT'S MAMMA

We had two of our original rabbits left and made use of them for the reason that they had already received irritating dosage in the mammary gland and we felt that they would be much more likely to show epithelial alterations than new animals. We accordingly took them from the males, treated them for a short time and put them with males again, and for the third time treated them with injections. Notwithstanding this severe treatment true stimulation of epithelium to adenomatous or carcinomatous growth did not result. Here are the notes made from the microscopic sections of one. The other was very similar.

Rabbit 58.—Injected six times dead degreased tubercle bacilli; put with male; injected five times; put with male, injected nine times. Did not conceive; mamma dissected off. The injected gland shows less activity than the untreated. A larger part of section surface of untreated gland shows active milk production. The lining of the ducts and skin surface shows greater tendency to drying and flattening in the treated glands. The epithelium is the same in both.

Guinea-pigs were treated with dead degreased tubercle bacilli, dead tubercle bacilli and living tubercle bacillus extract. Two guinea-pigs whose young had died were also treated with wax emulsion. The wax formed a ball mass in the gland and was encapsulated, thus having no effect on the epithelium.

The treatment given the animals injected with the first-named substances consisted of injection, then mating, and again injections. One (631) conceived and the mammary gland was removed as soon as the young could be separated from the mother.

Guinea-Pig 631.—Treated with dead tubercle bacilli three times, then mated, injected three times. Treated mamma presented low-grade but definite interstitial mammitis with distortion of acini and some attempts at reduplication of epithelial lining similar to that in adenoma; untreated mamma normal.

---

* Commonwealth of Pennsylvania Department of Health Laboratories.

Guinea-Pig 536.—Injected three times with dead tubercle bacilli, then mated, then twelve injections. Animal had an abscess in mamma between last two injections which were three weeks apart. Died from enteritis. Very little difference microscopically between the two glands. In the treated one the connective tissue is probably greater in amount than in the untreated: the gland lumina are wider and much secretion fills them up. No epithelium cell change.

Guinea-Pig 637.—Injected three times tubercle bacillus extract, mated, injected seven times. Died of enteritis. The only noteworthy difference between treated and healthy glands lies in the abundance of desquamated epithelial cells in the gland lumina of the former.

III AND IV. BRONCHIOLES AND HEPATIC BILE-DUCTS

The two structures may be considered together because they are influenced seemingly in the same manner. In last year's report we described how the bile-ducts became prominent, tortuous and apparently increased. We are now convinced that an actual increase in bile-ducts occurs and we believe that they arise from liver columns.

We have one section in which a bile-duct can be traced from liver column cells with their homogeneous pale purple staining protoplasm and uniformly blue nearly solid nucleus, into a well-formed seemingly old bile-duct with epithelium having deep blue vesicular nucleus and rarefied pale blue protoplasm. The exact point at which this newly-made duct assumes its basal membrane cannot be precisely determined but it occurs before the transition of the cell staining properties is complete. As discussed in a previous paragraph, connective tissue increase is quite pronounced in these livers and this new growth is most marked in the fields containing the newly-formed bile-ducts. The connective tissue does not penetrate the lobules farther than where the changes of liver columns indicate alterations of cells preceding the form of duct epithelium. The bile-ducts are very tortuous, and indeed so conspicuously ramified and distorted that the picture of cystic adenoma is closely simulated. There may be also papillary outgrowths in lateral section, but one cannot say yet that these are more than ramifications cut across.

In the bronchioles the changes are fundamentally the same. The epithelium lining shows, however, many more changes correspondingly than do the bronchioles as tubes. One cannot say that they are increased in number, but they are undoubtedly abnormally tortuous. The epithelium is reduplicated both regularly and irregularly. The glands of the larger bronchioles show changes suggestive of carcinoma simplex, although by search one can find a well-formed complete basal membrane.

Within the bronchiolar lumen, one may see papillomatous overgrowth of the epithelium, usually but not always accompanied by connective tissue stalks. Many desquamated whole and disorganized epithelial cells lie in the lumen. Similar pictures, but to a very mild degree, are seen in the large bronchi.

COMMENT

The results of our experiments with the purpose of stimulating superficial epithelium overgrowth by products of the tubercle bacillus have not been satisfactory.

At most there is but little overgrowth and that is best seen on the free surface where the irritant was applied locally. Here the tubercle bacillus products have behaved as most other mild irritants, producing a low-grade keratosis. On the other hand, in the internal viscera of animals injected subcutaneously or intraperitoneally with the tubercle product, a very decided influence is exerted on bile-ducts and bronchiolar epithelium, which can be explained only on the basis of some attraction relationship between epithelium and the tubercle bacillus. The following conditions, however, must be strongly emphasized. Animals receiving tubercle bacillus products into the peritoneum or beneath the skin show these changes clearly enough to be followed. Animals given living tubercle bacilli, either after or before the product, show the changes in liver and lung very well and in much farther advanced condition than when living tubercle bacilli are not given. Control animals receiving only living tubercle bacilli present changes to about the same degree as seen in animals receiving only injections of products. The deduction is therefore justifiable that a combination of living tubercle bacilli and a tuberclin is necessary to the great effect on epithelium. This is not true for endothelium, which seems to undergo rapidly the changes usual in unrestrained tuberculomata or in caseous tuberculosis.

We might hazard a conclusion that this helps to explain the benefit of tuberculin injections on tuberculosis of organs rich in epithelium and the rather less promising outlook for caseous lesions where endothelium predominates.

A THEORY FOR THE PATHOLOGIC PHYSIOLOGY INVOLVED IN DISEASE OF THE THYROID GLAND AND ITS THERAPEUTIC APPLICATION

EXPERIMENTAL STUDIES *

JOHN ROGERS, M.D.
NEW YORK

A SUMMARY OF WHAT IS KNOWN ABOUT THE PHYSIOLOGY OF THE THYROID

It is now accepted as reasonably certain that the thyroid discharges into the circulation a secretion which is of importance for many organs and tissues; that this exerts its effects directly on some and indirectly on others, possibly through the nervous system; that the formation of this secretion is the only function of the thyroid and that it has no other constructive or destructive attributes; that the physiologic activity of the thyroid secretion is dependent on an iodized protein or proteins and that it seems roughly proportionate in activity to its iodin content; that this secretion seems not to be destroyed during its utilization but to be reabsorbed by the thyroid with little or no loss; this fact in itself suggests the possibility of auto-activation of the gland.

It also seems to have been demonstrated that iodin starvation may produce simple goiter which can be interpreted as a compensatory hypertrophy in the attempt to supply a normally active thyroid product in the presence of a deficient ingestion of the essential iodin.

The thyroid secretion has some connection with oxidation, for by thyroid feeding in myxedema or cretinism the consumption of oxygen can be markedly increased. Likewise the amount of heat given off from the body can be correspondingly augmented. Conversely, experimental thyroidectomy leads to a diminution in the absorption of oxygen. This secretion also has to do with both carbohydrate and nitrogenous metabolism and cer-

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911. *The article is here abbreviated because of its length, but it appears in full in the Transactions of the Section and in the author's reprints.*

tain recent experiments[1] seem to connect nitrogenous metabolism in the liver directly with the thyroid. There has been much controversy about the iodin content of this gland in health and disease, but the most recent and correct determinations[2] seem to prove that the normal human organ contains on an average 0.3 mg. of iodin per gram of gland substance. In the thyroid of Graves' disease, however, this is decreased to 0.2 mg. or 0.1 mg. or even less, and the less the amount of iodin per gram of gland substance, as a general rule, the more severe are the symptoms. Nevertheless, if before the gland comes to analysis, the patient has been fed iodin in any form the quantity of this element within the gland may be greatly in excess of the normal.

That which may be called the physiologic chemistry of the thyroid is extremely interesting and important: if a number of fresh and normal human thyroids are ground and suspended in salt solution, to which a little thymol is added to prevent putrefaction, and stored in a refrigerator for several days and the coarser material strained off through gauze or a filter, an opalescent or cloudy filtrate is obtained. By the addition to this of some dilute acetic acid at ice-box temperature, there results a small amount of precipitate, which is a nucleoproteid. After removal of this product and half saturation of the filtrate with ammonium sulphate there can be obtained a much more abundant precipitate, which is a globulin. In a similar treatment of the pathologic thyroid of Graves' disease, which is far richer in epithelium and poorer in colloid than the normal gland, the nucleoproteid element is obtained in much greater quantity and the globulin in much less or scarcely at all. The nucleoproteid product can therefore be supposed to represent the epithelial portion of the gland and the globulin, the colloid material. The cross-section of a thyroid taken from a subject of acute toxemic hyperthyroidism presents a solid yellowish surface very different from that of the normal gland with its sponge-like areas of small depressions filled with a mucoid substance. Histologically the vesicles of the diseased organ are more or less filled with epithelium, either fully formed or disintegrating, and with cellular detritus; but there is little or no colloid. Chemically, as remarked before, this gland contains an abundance of nucleoproteid while the globulin is scanty or absent.

Somewhat analogous chemical and microscopic differences exist between the normal thyroids of the pig and sheep. The latter animals have much more globulin or colloid than nucleoproteid, while the pig gland, which is very rich in epithelium, yields a large nucleoproteid precipitate and comparatively little globulin. As regards the iodin content of these two substances, the nucleoproteid seems to contain more than the globulin, but this element is present in both products. If, however, the dissolved and suspended thyroid proteids, instead of being treated at ice-box temperature, are first warmed to 40 C. and then treated with 0.5 per cent. acetic acid, a much larger precipitate results than in the cold process, and the filtrate yields little or nothing on the addition of ammonium sulphate. The laboratory workers therefore doubt that there can be any difference in the physiologic activity between the nucleoproteid and globulin constituents of the thyroid, as their chief chemical difference appears to lie in the temperature at which they are precipitated. Nevertheless, there seem to be very marked physiologic differences shown by these two substances. If 10 to 15 minims of a 1 to 1,000 solution of the human thyroid nucleoproteid is injected subcutaneously into a normal individual at intervals of a couple of hours it invariably and soon produces tachycardia, accelerated respiration, cutaneous flushing, slight elevation of temperature with a subjective feeling of heat, sweating, tremor, insomnia and a sensation of "nervousness." The amount required to excite these symptoms varies considerably in different persons, but by increasing the dosage the symptoms can always be obtained and gastro-intestinal disturbances with diarrhea may be added. The symptoms produced by the injection of the thyroid nucleoproteid therefore correspond very closely with those which accompany overactivity of the gland or Graves' disease.

It should be noted that the ammonium sulphate precipitate or the globulin cannot be obtained entirely free from some admixture with the nucleoproteid material. Now when thyroid globulin solution is injected subcutaneously into a normal individual in the same dosage as the nucleoproteid, there seems to be little or no effect except a feeling of well-being, and a very large amount has to be administered and for a much longer time, to obtain the characteristic signs of thyroidism. But in certain abnormal individuals whose condition can be traced directly or indirectly to some disorder of the thyroid, this (impure) thyroid globulin may act as a dissipator of melancholic depression, as a means of slowing the pulse and respiration, of improving the resistance to infection, of checking diarrhea, as a cholagogue, a diuretic, an emmenagogue, or a sexual excitant. In general, it will often increase the quantity of the hemoglobin and the red cells better and more rapidly than iron or arsenic; it seems to be a far better tonic than the "bitters" or their alkaloids; it is more specific in gout and rheumatism than colchicum or salicylic acid. In fact, the enthusiastic endorsements of thyroid feeding found in literature for every imaginable ailment would be far more abundant if this thyroid globulin were more generally known and obtainable. Its best results are shown in hypodermatic administration; but for this purpose it is necessary to employ the material made from the human gland, as that from an unrelated animal like the sheep, if continued for any length of time, excites in man the formation of antibody, which neutralizes the foreign proteid.

The college laboratory, under the direction of Dr. Beebe,[3] has made tablets chiefly from sheep and pig thyroids which contain the combined proteids precipitated by acetic acid at room temperature from one or the other gland and standardized according to their content of iodized protein. The dosage is from 1/100 to 1/10 of a grain frequently repeated. The sheep thyroid contains far more globulin or colloid than that of the pig and seems more generally useful. The combined thyroid proteids in the tablet made from the pig gland is often essential, however, in certain conditions which are accompanied by a blood-pressure above 130 or 140 mm. of Hg but is much more likely than the sheep thyroid tablet to excite the characteristic signs of thyroidism; and in addition there seems not infrequently to be produced a peculiar subjective feeling of melancholy.

In passing it should be noted that the usual commercial thyroid tablets are made from the desiccated sheep's gland. As the thyroid rapidly autolyzes and as the globulin or colloid suffers most in this process, it is probable that the useful and active ingredient or ingredients may be extremely variable in amount and contain mostly if not entirely only the nucleoproteid element. This thyroid nucleoproteid, which with more or less reason is assumed to be the chief active ingredient in the commercial thyroid tablet and in the laboratory tablet of the pig thyroid combined proteids (and can be prepared approximately pure) is extremely valuable in cases of thyroid disease presenting more of the symptoms of myxedema than of Graves' disease but with a blood-pressure above 140 mm. of Hg. In thyroid disease with high rather than normal or subnormal blood-pressure the thyroid globulin or the sheep thyroid combined proteids often aggravate some of the symptoms.

---

[1] Schryver and personal communication from S. P. Beebe.

[2] Riggs: Jour. Am. Chem. Soc., May, 1910, xxxii, No. 5.

[3] The methods of fractional separation of the thyroid components are described fully in the Am. Jour. of Pharm., February, 1911, by S. P. Beebe.

To recapitulate briefly the physiology of what appear to be two dissimilar though closely related substances in the thyroid secretion, it seems that the nucleoproteid affects chiefly if not solely the sympathetic nervous system, while the globulin or colloid affects so many organs and tissues that for the purposes of the hypothesis it can be called universally activating. An analogy for this double or complex secretion can be found in that of the pancreas, and the comparison may lead to less distrust of the findings detailed above.

THE ANTITHYROID SERUM

Before proceeding further it is necessary to refer to the antithyroid serum which led to the development of the theory about to be offered for the physiology of the thyroid. It is made by injecting sheep or rabbits at intervals of a few days with the combined nucleoproteid and globulin obtained from the human thyroid gland. After about six weeks of this treatment the blood is drawn from the carotid, the serum separated and tested for "activity" and stored for use in sealed glass tubes in a dosage of about 1 c.c. Its specificity and the reasons for it have been given in previous communications[4] and need not be repeated here. This serum seems as specific and beneficial in its effects on the symptoms of acute toxemic thyroidism as is the antitoxin on those of diphtheria; but the convalescence is protracted, and after the subsidence of the acute symptoms the antithyroid serum must not be "pushed" unduly. In acute exacerbations of chronic thyroidism it must be used with caution and not beyond the period at which it seems beneficial. In the usual chronic case of exophthalmic goiter, except when the blood-pressure is high or above 150 mm. of Hg, it is slowly beneficial and often curative when administered at intervals of two or three days and continued for weeks or months. It cannot with safety be administered oftener than once in twenty-four hours, and if at any time at the end of two or three days it has intensified rather than alleviated symptoms it should be stopped.

THE RELATIONSHIP OF THE CHROMAFFIN SYSTEM TO OTHER ORGANS AND ITS CONNECTION WITH DISEASES OF THE THYROID

The chromaffin system is an extremely interesting organ or group of organs, apparently belonging to both the nervous and secretory systems in that it is composed of certain cells distinguished from others by a characteristic staining reaction with the salts of chromium. These cells originate from the same embryonic source as the sympathetic nerves, namely, the neural ectoderm, and are found in larger or smaller collections in juxtaposition with these nerves all the way from the base of the skull to the bottom of the pelvis. The largest individual groups of them exist in the medullary portion of the adrenal glands, from which their active ingredient or product, epinephrin, is derived. This seems limited in its effects to the terminal filaments of the sympathetic nerves. Although the aggregations of the chromaffin cells which produce the epinephrin do not correspond exactly to secreting glandular tissue, they must nevertheless be regarded as having a secretory function. Furthermore, some recent experiments by Cannon and others indicate quantitative variations in the blood from time to time of the adrenal or chromaffin system product and hence it is reasonable to infer the possibility of functional derangements of this system which correspond to what is known to exist in the case of the thyroid. The sympathetic nerves, it should be recalled, supply only unstriped muscular fibers and secretory epithelium, of which by far the greatest amount is concerned with digestive and nutritional processes. Epinephrin may thus activate or inhibit the purely nervous impulses which, in addition to the chemical stimuli conveyed through the circulation, regulate the interaction of the different organs and especially the gastro-intestinal tract, the pancreas and liver. The most abundant and easily demonstrated nerve-supply of the thyroid and pancreas is from the sympathetic.

The (pig) adrenal gland can be treated like the thyroid and the nucleoproteid material thus obtained differs from epinephrin in having no local vasoconstrictor effect, while it lowers blood-pressure instead of raising it in certain atypical conditions accompanied by thyroid disease. Those cases in which this product is extremely beneficial or essential have goiter and more of the signs of myxedema than of Graves' disease, although there may be a greater or less degree of tachycardia, a blood-pressure above 140 mm. of Hg, cutaneous pigmentation, and gastro-intestinal disturbance in the form of diarrhea or recurring attacks of nausea, vomiting and diarrhea. If there is in addition headache, a combination of adrenal nucleoproteid and thyroid nucleoproteid will generally prove most helpful.

THE SYMPTOMS REFERABLE TO THE CHROMAFFIN SYSTEM WHICH MAY INDICATE ITS PARTICIPATION AND FUNCTIONAL DISEASE IN DISORDERS OF THE THYROID

The secreting portion of this system, or the chromaffin cells, are generally believed to produce epinephin or some closely allied substance or substances which apparently vary in amount in the circulation according to the bodily needs. The secretory portion of this mechanism must be subject to the same general laws as other organs, and hence must suffer from functional and structural disorders. The general picture furnished by Addison's disease supplies a very indefinite and uncertain standard but is the only one clinically recognized. The quantitative test for epinephrin by the instillation of a drop of blood or serum into a freshly excised frog's eye and noting the consequent degree of contraction or dilatation of the pupil, does not seem satisfactory. The destruction of the medullary portion of the adrenals apparently leads to a peculiar bronzing or pigmentation of the skin and mucous membranes, most marked about the nipples and genitals and in the mouth and on the hands and face; the muscular weakness is marked; the blood-pressure is low and the pulse rapid. Anorexia, nausea, vomiting and diarrhea are common. The most constant result of electrical stimulation of the adrenals in dogs is a pronounced muscular tremor, extreme tachycardia, accelerated respiration and a rise of between 1 and 4 F.

in temperature within half an hour, and a marked rise in blood-pressure which seems more pronounced than that due to fear or pain. In Graves' disease so many of the symptoms are traceable to stimulation of the sympathetic that it formerly was described as a neurosis of this system. The cutaneous flushing, the sweating, and the tachycardia are the most distinctive. In the absence of other known causes, an elevation or depression of the blood-pressure and cutaneous pigmentation and perhaps the converse, or extreme pallor, must also be traced to the sympathetic of chromaffin system. It was stated above that the thyroid nucleoproteid seemed limited in its effects to stimulation of this system and that the thyroid globulin in the same dosage showed none of this peculiar activation. Hence when there is a demonstrable excess of nucleoproteid in a given thyroid secretion it is reasonable to ascribe the origin of the symptoms referable to the sympathetic, ultimately to the thyroid, and in the absence of such an excess of thyroid nucleoproteid they should be traceable directly to a functional disorder of the chromaffin system.

The presence of a goiter will often supply the clue for unraveling many obscure conditions.

THE RELATIONS OF THE PANCREAS TO THE THYROID, LIVER AND CHROMAFFIN SYSTEM

The digestive action of the pancreas needs no review, and it remains only to recall that there is a reasonable certainty of the relationship existing between the hydrochloric acid of the stomach, the secretin or prosecretin of the duodenum, the pancreas, its trypsinogen and the enterokinase of the small intestine. From the results of the experiments outlined above[5] it seems probable that at least some of the intestinal secretion of the pancreas is absorbed into the portal system and being thus carried to the liver exerts an important direct effect on the chemical processes in this organ. It is also reasonably certain that the pancreas produces an internal secretion, probably from the islands of Langerhans, which has a close connection with the adrenals and sympathetic nervous system. This has been demonstrated with more or less certainty in the great number of experiments dealing with glycosuria, particularly those of Opie, who extirpated all but a small portion of the pancreas and found no glycosuria until this remnant was removed. The remnant contained only the islands of Langerhans.

The investigations on glycosuria have also shown that the thyroid is concerned in the process through some apparently inhibitive action of the pancreatic by the thyroid secretion. Furthermore, all the evidence at hand strongly suggests that the closely interdependent thyroid, pancreas and chromaffin systems consummate their relations in the liver. Hence it is extremely probable that disease cannot exist in any part of this group without affecting more than one of its components. These components may be and probably are connected with other organs similarly associated in function, and therefore, therapeutics directed at the thyroid alone may be even harmful if the thyroid is not the primary source of the difficulties. Apparently goiter or symptoms referable to the thyroid may occasionally be entirely secondary to other disturbances, and the superficial deformity seems often to be only a hypertrophy which is compensatory to a failure elsewhere. A pancreas nucleoproteid can be prepared from the ground-up gland suspended in salt solution like that from the thyroid and adrenals. Clinically, it is a valuable and sometimes an essential adjuvant in the treatment, particularly in some cases of myxedema which are accompanied by headache, insomnia, constipation and persistent asthenia with loss of flesh and strength. The dosage is from about ⅛ to 1 grain, frequently repeated and generally used with the combined proteids of the sheep thyroid.

In addition the commercial enzymes or extracts of the pancreas, especially trypsin, administered by rectum or by mouth, are often useful as sedatives in all stages of Graves' disease.

THE SYMPTOMS WHICH MAY INDICATE PARTICIPATION OF THE PANCREAS IN THYROID DISEASE

The symptoms referable to functional or structural disease of the pancreas are notoriously unreliable. Nevertheless, as extreme fatigue impairs the functional activity of all organs, it is fair, under these conditions, to infer a decrease in the pancreatic product. The insomnia and constipation which are so constant in *incipient or early* hyperthyroidism, can be regularly relieved by the administration, either by mouth or by rectum, of one or another preparation from the pancreas, and hence these vague signs may be those of pancreatic insufficiency. The Cammidge reaction and tests of the stools in my hands have proved negative in disorders of the thyroid in which the pancreas may be supposed to participate.

Without the coexistence of thyroid symptoms or a perceptible goiter it would be clinically impossible to recognize the cases in which pancreas feeding can give the greatest benefit.

THE COMPARISON OF SYMPTOMS IN DIFFERENT FORMS AND STAGES OF THYROID DISEASE TO SHOW THE VARIATIONS IN THEIR PROBABLE ORIGIN AND CONSEQUENTLY IN THE THERAPEUTICS REQUIRED

In the development of the hypothesis and for therapeutic purposes, it is necessary to contrast the symptoms of Graves' disease, or hyperthyroidism, and those of myxedema, or hypothyroidism. The indications of defective or deficient thyroid globulin can then be pointed out. An excess of nucleoproteid in the thyroid secretion seems always to be shown by stimulation of the sympathetic nervous system which is revealed chiefly by tachycardia and cutaneous vasomotor irritability.

SMYPTOMS[6]

Hyperthyroidism with excess of thyroid globulin:	*Hypothyroidism with defective or deficient thyroid globulin:*
1 History of fatigue and slow onset.	1. The same.
2. More common in adolescence than in middle life and in women.	2. More common during and after middle life and in women.
3. Cutaneous flushing; tachycardia; manifest overaction of [illegible] vic. [illegible] by [illegible] 120-130.	3. Flushed skin over malar prominences only, marked pallor elsewhere; slow pulse; blood-pressure usually below 120.
4. Mental instability and excitability rather than mental alertness; tremor; restlessness; quick, jerky movements *of extremities*; insomnia.	4. Mentality sluggish, rather than dull; headache; insomnia with changes to somnolence only in terminal stages; slow movements.
5. Muscular weakness and inability to withstand ordinary fatigue.	5. The same.
6. Exophthalmos generally present in some degree, and the more marked it is the worse is the prognosis. It is often absent in the early stages.	6. No exophthalmos except in those who have passed through a preceding Graves' disease. In place of it there is a characteristic puffiness and edema around the eyelids and in the supraclavicular regions and on the back of neck and below the knees.

SYMPTOMS—Continued

Hyperthyroidism with excess of thyroid globulin:	*Hypothyroidism with defective or deficient thyroid globulin:*
7. Goiter of variable size and consistency. Its vascularity and density give some indication of the relative importance of the thyroid in the general disturbance; goiter is often imperceptible in the early stages.	7. Goiter is common, but by its consistency and absence of vascularity suggests a functionless organ.
8. Appetite abnormally good and out of proportion to the evident poor nutrition, movements regular or diarrheic. Thirst constant.	8. Appetite poor; apparently good nutrition. Constipation. No thirst.
9. Skin moist with a subjective feeling of heat.	9. Skin dry and scaly; subjective feeling of cold.
10. Temperature 99 to 101.	10. Temperature subnormal.
11. Blood shows relative lymphocytosis, anemia slight or absent.	11. Negative, anemia regularly.
12. Menstruation irregular or absent.	12. Regular but scanty, occasionally excessive.
13. Urine in nitrogen partition shows excess of creatin and diminished creatinin.	13. Negative; albumin sometimes present.

As typical Graves' disease may terminate in a typical myxedema there are in the intermediate stages many examples of the coexistence of both of these conditions. Clinically these states are remediable, not by measures designed to suppress the thyroid, like the antithyroid serum and partial thyroidectomy, but by feeding with thyroid globulin or the combined sheep thyroid proteids, which contain an excess of this substance. The inference is plain, therefore, that there is a deficient or defective colloid. The chief symptoms which indicate the necessity are headache, especially in the morning, anorexia, constipation and a dry skin, especially over the elbows and knees, and edema about the ankles.

THE HYPOTHESIS

Normally the thyroid, through a small but important part of its secretion, is supposed to activate specifically the chromaffin or sympathetic nervous system, and through the larger portion of its product every other organ and tissue in the body. The word "activate" is used intentionally in a general sense to signify some constant unknown chemical reaction which is of importance to the functional activity of every part of the body, as it is difficult to conceive of a secretion having one effect on this organ and another on that. And the thyroid evidently is concerned in so many metabolic processes that its influence cannot be excluded from any. It follows, therefore, that conditions which call for great functional activity in any particular organ or group of organs must require some corresponding increase in the functional activity of the thyroid and often force it to undergo a compensatory hypertrophy. This may result more easily if the gland possesses some congenital or acquired defect which makes its output less efficacious than it should be. The goiters which occur in young girls at puberty or in women during pregnancy or at the menopause can thus be explained as hypertrophies of a possibly weak organ to compensate for an unusual demand on the thyroid secretion, while the so-called endemic goiter found in certain localities may be the expression of an attempt on the part of the thyroid to compensate for a defect in itself or elsewhere which is dependent on a starvation or superabundance in some element essential in the metabolism of one or more organs. This means that all goiters, except the true tumors of the thyroid, though they may originate in many different ways from defective metabolism in the thyroid itself or any other functionally associated organ, have essentially the same cause in an increase or attempted increase in thyroid function. The later degenerative changes which may supervene in the gland are side-issues, although they may be of great importance, in that these changes, by destruction of the portion of the gland still capable of normal function, may promote the enlargement and degeneration of this part, or by pressure on adjacent structures, chiefly the trachea, so interfere with general nutrition as to have the same effect as the primary fault.

The increase of function implies a consequent fatigue, the effects of which have been studied chiefly by electrical stimulation of the salivary glands. In these there is at first a greatly increased and approximately normal flow of secretion according to the nerve employed, but it soon becomes watery and of poor quality and finally ceases altogether and cannot be reexcited until a considerable period of rest has been allowed. All the clinical evidence strongly suggests fatigue in one form or another as the exciting cause of hyperthyroidism. The production of a normal secretion or colloid material, of course, depends on the vitality or biochemical capacity of the thyroid epithelium; and, as iodin is an essential ingredient of its product, the biochemical relationship of the epithelium with this element should suffer according to the degree of fatigue imposed on the gland. In the fractional separation of the thyroid proteids the pathologic gland of hyperthyroidism, as remarked before, yields a far more abundant acetic acid precipitate than the normal organ and much less of an ammonium sulphate precipitate. The quantities vary within certain limits, depending somewhat on the temperature and concentration of the solutions employed, but in general the quantity of the acetic acid precipitate is in direct proportion to the severity of the hyperthyroid symptoms, and the most prominent of these are traceable to the chromaffin or sympathetic nervous system. Qualitative variations in the product of the thyroid of Graves' disease, though probable from analogy and from the microchemical appearances of the gland, cannot be demonstrated as well as can these quantitative changes in its product. It is assumed, therefore, with more or less reason, that in Graves' disease fatigue damages the biochemical relationship of the epithelium with iodin and in an ineffective attempt to metabolize this element properly, the epithelium proliferates too rapidly and disintegrates, and, instead of a colloid containing the normal proportions of iodized proteids, there results one in which there is an excess of one or more elements and a deficiency of others. Specifically there seems to be an excess of one, designated here as a nucleoproteid, which is believed to activate only the chromaffin system, and in the most severe forms of the disease a deficiency of the globulin component of the secretion although in the milder forms of the disorder this also may be more or less abundant, but possibly of inferior quality. In consequence of this excess of nucleoproteid the whole sympathetic nervous system which supplies secreting, glandular epithelium is unduly stimulated and one or more vicious circles are immediately started, which perpetuate the process. Auto-activation of the thyroid through its sympathetic innervation is suggested by the injurious effects of (commercial) thyroid feeding in active hyperthyroidism, as well as by the benefits obtainable from surgical interference. At the same time the globulin portion of the secretion which is supposed to be universally activating may return in the circulation to its source, and, when superabundant, as in the milder forms of hyperthyroidism, may stimulate the epithelium to a pathologic extent. The similar activation of the sympathetic, by the thyroid nucleoproteid and probable fatigue which follows this stimulation of the important organs concerned in digestive processes, should impair the general nutrition. and with it that of the thyroid, and thus add to its injury and abnormal activity. If the supposed compensatory hypertrophy and overactivity of the thyroid was started by a primary defect, for example. in the chromaffin system or the pancreas, as is conceivable and seems probable from clinical experiences with certain cases, attempts at relief of the thyroid fatigue and its consequent excessive stimulation of the sympathetic are always logical though seldom curative. Patients with glycosuria and comparatively mild signs of Graves' disease or with symptomatic Addison's disease and moderate thyroidism are suggested as belonging in this class. But feeding thyroid to a diabetic individual with the object of relieving the apparent strain on the thyroid is dangerous.

The existence of hyperthyroidism without any perceptible goiter seems to indicate that the gland is so defective or so fatigued as to be unable to hypertrophy, and in general, such cases will be found to have a worse prognosis than those in which a considerable enlargement has occurred before the constitutional manifestations appear, and when recovery from the thyroidism takes place, sooner or later signs of myxedema commonly follow.

In myxedema it is believed that a fatigue of the thyroid has been brought about in some one of the same several ways which are apparently the exciting cause of simple goiter and of hyperthyroidism. But the epithelium in its attempt to metabolize iodin, instead of multiplying, is unequal to any effort at compensation and atrophies. The not infrequent termination of simple hypertrophy of the thyroid and of Graves' disease in myxedema and the injurious effects of fatigue in general on the disorder, as well as the therapeutic experience of thyroid feeding, particularly with the active ingredients of the gland in their normal proportions, which may be supposed to relieve the strain on the organ, all unite to indicate a glandular fatigue as the cause of myxedema. When symptoms of Graves' disease and myxedema coexist, as often happens, it seems probable that certain portions of the thyroid are more injuriously affected by fatigue than others, and, while one area attempts to compensate for the excessive demands on the biochemical capacity of the epithelium by its proliferation, another is incapable of response and the epithelium atrophies. Or, inasmuch as the symptoms of Graves' disease more frequently precede those of myxedema, the latter is simply the expression of the terminal stages of the glandular fatigue and becomes manifest in the epithelium serially in the order of its individual vitality.

THERAPEUTICS

This hypothesis, based on fatigue of the whole organism, and especially on that of the components particularly concerned in general nutritional processes, and on the consequent variations in the quality and quantity of the products of these components, supplies a rational foundation on which to formulate measures designed either to check a pathologically overactive thyroid or to aid a defective one.

The primary requisite is rest for the gland, and that for sufficient time to allow its epithelium to regain its ability to metabolize iodin properly. To obtain this the superabundant thyroid nucleoproteid, and probably the thyroid globulin, must be cut down, not only to relieve the thyroid of the constant auto-activation, but to check the abnormal stimulation through the sympathetic of the thoracic and abdominal organs. While this is being accomplished, the presumable strain on the thyroid, whose secretion is supposed to be in constant and universal demand, must be relieved by feeding, preferably with the combined sheep thyroid proteids, which contains a preponderance of globulin, in a dosage of approximately from 1/100 to 1/10 grain frequently repeated. The probability of auto-activation of the gland must be borne in mind and the thyroid feeding kept constantly just below the point at which it intensifies the symptoms.

In addition attention should be given to all associated errors, especially in the gastro-intestinal tract, in order that the nutrition, irrespective of the hypothetical functional disorders of the pancreas and adrenals, may be improved, and thus by improving the general nutrition improve the nutrition and the functional capacity of the thyroid. Appropriate "organ therapy" ineffective as it often must be from our ignorance of its mechanism, seems theoretically best.

Patients with thyroidism who show a blood-pressure above 140 mm. of Hg and some signs of myxedema, especially headache, insomnia, constipation, a dry skin and asthenia, generally are more benefited by feeding with the combined pig thyroid proteids or the commercial tablets made from the desiccated gland, both of which contain a preponderance of the nucleoproteid element, than by the administration of thyroid globulin or the combined sheep thyroid proteids. Or the adrenal nucleoproteid, alone or combined with the thyroid nucleoproteid, may prove most satisfactory, especially if there is diarrhea and much cutaneous pigmentation and the symptoms directly referable to thyroid activity are not marked.

One or another form of pancreas feeding seems usually a necessity in myxedema and is generally beneficial in thyroidism although occasional instances of intensification of symptoms may occur in typical Graves' disease.

As remarked before, the antithyroid serum is almost as specific in cases of acute toxemic thyroidism as is the antitoxin for diphtheria. Theoretically at least, by its cytotoxic element it checks or inhibits the abnormal proliferation of the epithelium and by its antiglobulin neutralizes the colloid. But after the subsidence of the acute symptoms it should not be pushed, as it may damage the already weakened gland. Rest and supporting therapy are more often indicated.

The serum should be used with more caution in the frequent acute exacerbations of a chronic thyroidism. It is exceedingly valuable in a crisis, but a gland which may be supposed to be almost devitalized although dangerously overactive, can withstand but little interference.

The operation of ligation and division of the blood-vessels and nerves of the thyroid at favorable opportunities is both theoretically and practically indicated, as it insures rest for the gland by cutting off not only auto-activation, but all stimuli. The operation has not received as much attention as it should because the two inferior thyroid arteries are usually not disturbed and are often larger and so more important than the superior. All four vessels with their accompanying nerves and the superior thyroid veins (there are no veins accompanying the inferior arteries) can be cut under local anesthesia and without appreciable risk, provided not more than two are cut at one sitting.

Partial thyroidectomy in exophthalmic goiter apparently cures by removing at once the excess of abnormal secretion and so allowing the remaining portion of the gland to rest and regain its ability to metabolize iodin. But it will invariably fail to cure when undertaken in a symmetrically diseased gland and unless the convalescence is most carefully guarded. To be successful the portion of the gland which is allowed to remain must possess excellent vitality and show some approach to normal structure; otherwise the patient is left with only half a gland which is even less able to withstand fatigue than the whole organ was originally.

Thyroidectomy is essential, however, in cases of localized or partial thyroid disease in which the diseased tissue, not only by constant auto-activation of the whole gland by the secretion from its abnormal portion, but by pressure on the approximately normal portion of the gland by the diseased part so damages it that complete degeneration may follow. Furthermore, pressure on surrounding structures, especially the trachea, may so interfere with general vitality that this alone renders operation imperative. At the same time in the presence of dyspnea from goiter, operation will benefit or cure any co-existing thyroidism through improvement in the general, constitutional nutrition, which in turn benefits the thyroid and enables it to regain its ability to metabolize iodin properly.

But radical operation should be undertaken with far more caution than is usually the case and should be followed for a long time by thyroid feeding, preferably with the combined sheep thyroid proteids, to relieve the strain on the remaining portion of the thyroid and enable it to undergo the necessary compensatory hypertrophy.

Rest is as essential in the successful management of hypothyroidism as it is in hyperthyroidism. But the treatment of myxedema, especially in some of its atypical aspects, is far from being as simple a matter as seems usually believed. The ordinary commercial thyroid tablets, when given in sufficient amount to relieve some of the symptoms, will often excite the characteristic signs of thyroidism apparently by auto-activation of the gland through its sympathetic nerve-supply. This results in an exaggeration of the fatigue and in a worse condition than the myxedema. The combined thyroid proteids of the sheep gland, with their abundance of the globulin element, are to a large extent free from this disadvantage, but even these may fail to prove satisfactory. If there are indications of probable pancreatic deficiency in persistent headache, insomnia and constipation, it will generally be found that the addition of one or another pancreatic preparation will be successful. Or if there is a high blood-pressure with headache and occasional or constant diarrhea and cutaneous pigmentation or extreme pallor without noticeable anemia, the adrenal nucleoproteid, alone or in combination with the thyroid nucleoproteid, is often most beneficial. There are some cases, however, in which nothing seems capable of affording benefit except a solution given hypodermatically of the thyroid proteids obtained from the human gland.

The simple hypertrophies of the thyroid which are most common in young people, especially girls, are, of course, to be regarded as a protective rather than a pathologic phenomenon; except that the hypertrophy is compensatory to some deficiency in the thyroid itself or the organs associated with it, and as fatigue is a part of the process, rest is essential in the treatment. In addition, every care must be expended to recognize and remedy all nutritional errors. But these hypertrophies carry with them the ever-existing dangers of thyroidism, and should, therefore, be regarded with concern and seldom or never dismissed as of trifling importance. Nor, on the other hand, should they be subjected to radical thyroidectomy, which ruthlessly destroys the attempted compensation and often does irreparable damage.

102 East Thirtieth Street.

FACTORS INFLUENCING THE SAFETY OF OPERATION FOR GOITER *

MARTIN B. TINKER, S.B., M.D.
ITHACA, N. Y.

No form of treatment for goiter has stood the test of years as has surgery since 1885, when Kocher reported the first considerable number of operations. Numerous patients treated for years by drugs, serums and other measures have later sought relief in surgery, and the number of enlightened internists who, like Osler, refer their patients for operation after three months' unavailing medical treatment is rapidly increasing. A further increase in the amount of goiter surgery will depend on our success in convincing the general practitioner and the patient of the safety of operation. A study of my recent methods with no mortality in 167 consecutive cases in comparison with earlier work, which was much less successful, may offer some suggestions to those interested in this subject.

EARLY OPERATION FOR SAFETY

As in many pathologic conditions, the safety of the patient may depend in large part on the early recognition and appropriate treatment of the disease by the general practitioner, and if this is unsuccessful, refering patients early for operation. If the physical condition is fairly good, the risk of surgery is slight. On the other hand, with delay there is danger of development of hyperthyroidism; of a dilated heart with irregular and intermittent pulse; a wrecked nervous system; eyes permanently bulged; growth of an intrathoracic goiter until emphysema has developed. No surgeon can operate with entire safety in such cases. The safety of the patient is in the hands of the internist who first sees and advises him.

PRELIMINARY STUDY OF DOUBTFUL CASES

The general physical examination is of greater importance than in most borderline conditions, and for the safety of the patient, it should be thorough and comprehensive. In our preliminary investigation, we have not merely the question of diagnosis of the disease with definite certainty that operation is indicated as soon as the diagnosis is established. A number of doubtful cases are entitled to further trial of medical treatment. With another group, the safety of our patient depends on deferring surgical treatment: a patient who may be greatly benefited by a suitable operation after a week or a month's proper preparatory treatment, might very readily succumb to an immediate radical operation. A third group of patients are best suited for the many-stage operation. In a fourth group of cases, immediate partial thyroidectomy may be advised with entire safety.

A decision as to what can be done with greatest safety should not be based on any single factor, for example, a study of the blood, but on the entire clinical

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

picture. Wilson and several other recent observers have questioned the value of blood-findings in goiter. The blood has been examined in the majority of my own cases by competent laboratory men, a considerable number of them from the laboratory of Dr. S. H. Burnett of Cornell University, whose book on the blood will be familiar to most workers in this line. The results have been entirely confirmatory of Kocher's statements, and my experience leads me to consider the preliminary blood examination of great value in determining what our course should be in the advanced exophthalmic cases. In nearly moribund cases, lymphocytosis may well be absent because the patient's power of reaction is destroyed. After operation, I have found in a number of examinations that the blood-picture again becomes normal.

The use of the *x*-ray as a curative measure has gained relatively few adherents and as a preliminary treatment is no longer advocated. In diagnosis it may prove an important aid, however. There can be no question about the possibility of outlining the position of many intrathoracic goiters by the *x*-ray. It may readily add greatly to the safety of operation to know exactly the location of some of the difficult growths. In connection with the *x*-ray diagnosis it is interesting to note that Garre of Bonn and other German workers believe that enlargement of the thymus has an important influence in the development of exophthalmic goiter, and Schultze has been able to outline the thymus in eighteen out of twenty cases with the fluoroscope.

The preliminary study is much more valuable when several workers, experienced from observation of a large series of cases, compare their findings. The internist who has examined a considerable number of cases preliminary to operation and who has kept himself informed as to the outcome in these cases; the laboratory man who makes the blood examination, which should include differential count and coagulation time as well; also examination of the urine; and the surgeon who sees most of the actual conditions inside the neck, should, for the safety of the patient, compare their findings. A single general physical examination is not always adequate to give an idea as to the safety of operation.

THE FATIGUE TEST

The character of the pulse, blood-pressure, heart's action, even the differential blood-findings and conditions of the urine may vary greatly at different times and under different conditions. Examination of a patient who has been kept at perfect rest for days or weeks and whose heart's action is relatively quiet and regular, may give an erroneous impression as to the safety of operation. On the other hand, a patient coming from a distance, fatigued and nervously distressed by a long journey, strange surroundings and what is regarded as an important consultation, may easily give the impression of a far worse operative risk than is actually the case. The exertion of going up stairs somewhat rapidly will give a better idea as to how the circulation will behave on the operating table in some cases. In other cases the exercise should be far less active; and in some it is evident that no extra exertion would be safe. After taking a somewhat long and careful history or after exciting conversation an idea may be gained of nervous and mental condition. Those not equal to an extra fatigue are obviously unfitted for radical, if for any, surgery; those reactng poorly are equal only to slight operations. Such tests of the effects of slight fatigue will often show that the patient is less fit for operation than at first appears.

The safety of operation, if after careful preliminary study immediate operation is decided on, is influenced by many of the factors under consideration before any surgical operation: the skill and experience of the surgeon, the care as to aseptic and antiseptic preparation; the choice of anesthesia to be used, etc.

ANESTHESIA

Probably a large proportion of the patients could be safely operated on by an experienced surgeon under almost any form of anesthesia, but to save the patients whose cases are critical some discrimination is necessary. Kocher for many years has used local anesthesia as a routine method with general ether anesthesia in a few selected cases. Mayo uses local anesthesia for some excisions, for ligations in toxic cases, and ether by the drop method as a routine, but so light an anesthesia that the patient frequently struggles and sometimes *protests. Crile uses local anesthesia in combination* with scopolamin and morphin hypodermically and nitrous oxid inhalation. Ochsner prefers to put the patient well under ether before beginning the skin incision and then completes the operation without further anesthesia. An increasing number use local anesthesia in selected cases. Practically all experienced men who use general anesthesia really only partially anesthetize their patients. The majority of operators still have a favorite general anesthesia which they employ in a favorite way (which varies anywhere from the open-drop method to breathing in and out of a closed bag), and this anesthesia and method they use in every case.

That such undiscriminating use of general anesthesia in goiter has resulted in many needless deaths, can scarcely be questioned. The angulation and compression of the trachea which is unavoidable with many growths, the rise in blood-pressure greatly increasing hemorrhage, the not infrequent degeneration of parenchymatous organs, the profound toxemia in the advanced exophthalmic cases—all of these factors certainly contra-indicate general anesthesia in many cases. The fact that the experienced men mentioned use such very light anesthesia or partial anesthesia really concedes the risk of general anesthesia. The fact that at least one-third of the goiter operations can be performed without any serious discomfort under proper methods of local anesthesia, and the number of obvious advantages in this mode of procedure, lead me to prefer it as a routine. Not only is there no interference with respiration in deeply located growths and less danger in toxic cases, but in all cases the hemorrhage is greatly reduced and the danger of injuring the recurrent laryngeal nerve is almost entirely obviated. I have not found it necessary to tie or strap my patients to the operating table as some do who prefer partial anesthesia. Many patients, even those who make considerable complaint, are really deeply in scopolamin-morphin sleep and do not later remember anything of the operation. It is frequently necessary to shout loudly to them to get a reply when working near the recurrent laryngeal nerve. Kocher has operated on over 600 consecutive simple goiters under local anesthesia without loss of life. I am not aware that so large a number of operations has ever been performed under general anesthesia without loss of life.

Crile's work seems to show that nitrous oxid-oxygen is the safest of the general anesthesia methods. In perfectly simple cases in which it is evident that general anesthesia would be relatively free from risk, I now give my patients the choice of nitrous oxid by the Gatch method or local anesthesia, though always expressing my preference for the local method. In very young or nervous patients, I also frequently use nitrous oxid. In quite a number of cases, it is of advantage to use local anesthesia for the major part of the operation, giving nitrous oxid gas at those stages in which there is discomfort from digging out very deeply located or adherent growths. If any general anesthesia is to be used, the necessity for care and experience is evident. With the local and gas anesthesia, so little gas is given, and over so short a time in most cases, that it adds slightly if any to the risk.

Control of hemorrhage was one of the bugbears of thyroid surgery in earlier days. While this is well managed in our best clinics, the essentials deserve mention, for nothing is more important to safe thyroid surgery. Picking up all bleeding points, as is necessary for accurate anatomical dissection, so that the field may not be obscured by smearing with blood, reduces hemorrhage to a minimum. In case of important bleeding, packing with gauze while the surgeon goes to another part of the field temporarily, usually makes it easy to secure small vessels later. The half-sitting posture at present used by practically all who are doing any considerable number of goiter operations greatly reduces bleeding, specially venous hemorrhage. Dislocating the gland from its bed, thus giving ready access to the deeper blood-supply early in the operation, is a great advantage in most cases. The rise in blood-pressure incident to the use of ether or nitrous oxid greatly increases hemorrhage, while the dryer and cleaner field under local anesthesia makes it easier to immediately secure the main arterial and venous trunks. This greatly increased ease in the control of hemorrhage is one of the greatest advantages of the use of local anesthesia.

ASEPTIC AND ANTISEPTIC METHODS

Perfect wound healing, desirable in all surgery, is specially important for the safety of goiter surgery, for these toxic hyperthyroid patients show very little resistance to infection. Iodin being readily absorbed by the skin (aside from its relative inertness as an antiseptic) is contraindicated in skin disinfection for the reason that there is already too much thyreoiodin in the circulation. The development of exophthalmic symptoms from local use of iodin painted on the skin or applied as an ointment has recently been mentioned.[1] For the same reasons iodin catgut should be used sparingly in toxic cases. When gauze is used in packing the wound in the stage operation, plain gauze has proved entirely satisfactory. Iodoform gauze would certainly seem contra-indicated because of the iodin often set free from it. The use of Harrington's solution or other strong antiseptics to swab out the wound, with the idea that absorption of thyroid secretion is thereby lessened, has now been discarded by its originator.

ANATOMY

Familiarity not only with the normal but with at least the most common anomalies is highly important for safeguarding important function as well as life. Anatomic structures entering into every goiter operation, familiar to all workers in this field, but seldom requiring consideration in other operations of general surgery, are the platysma muscle with its influence in producing an invisible, or if neglected, an ugly scar; the superior cervical nerves, which if thoroughly infiltrated with anesthetic solution give freedom from pain in the entire superficial dissection of the neck; the descendens hypoglossi nerve (formerly descendens noni), the motor nerve-supply of the sterno- and omohyoid muscles and the thyrohyoid muscles. The relations of the very common intrathoracic goiters to the pleura and the innominate and subclavian vessels and to the deep sympathetic, vagus and phrenic nerves may be of vital importance to the safety of our patient. Probably every experienced worker in this field has met troublesome hemorrhage from tearing off branches of these deep vessel trunks and disturbances of breathing from tugging on the respiratory nerves. Upward prolongations and deposits of masses of thyroid tissue in the region of the base of the tongue, the territory of the thyroglossal duct in the embryo, while not as common as intrathoracic goiter, is not infrequently met in my experience (*5 per cent. of my first series of 100 and 2* per cent. of later series). The importance of the relations of the recurrent laryngeal nerve and the parathyroids has called forth a number of interesting papers. Probably the importance of injuring the parathyroids has been somewhat exaggerated, but if the thyroid is stripped from its capsule along the inner and posterior surface, the danger of injury must be slight. Saving the posterior capsule also safeguards the recurrent laryngeal nerve.

TEAM WORK

Team-work is as important for surgery as for any college crew or football team. No surgeon, however skilful, can do certain difficult operations to advantage without skilled assistance. Good team-work may easily make the difference between death or recovery in operations for desperate goiter. The essential members of the team, starting from the surgeon, are the assistant, operating-room nurse and the anesthetist, if general anesthesia is given. The surgeon who operates with an assistant, nurse and anesthetist of his own choosing, selected not on the basis of competitive examination but on tried fitness, has the decided advantage over the surgeon working with a team constantly changing personnel or with no team at all.

Great things could undoubtedly be accomplished for the progress of surgery in this country by the establishment of long-term surgical and medical resident services and more or less permanent assistantships in more of our leading hospitals, instead of the present system of short-term internships with the resulting horde of half-trained and ambitious men who come out to get their surgical experience at the expense of their patients. The long-term resident plan in Europe has been at the foundation of much progressive and efficient clinical work; it gives the trained team-work necessary to the highest success in much besides goiter surgery.

THE MANY-STAGE OPERATION

The situation in goiter surgery is quite different from that in surgery in many parts of the body. In the treatment of cancer of the stomach, it would be impossible to divide our operation into stages, opening the abdomen at one time, ligating a few important vessels at another and completing the operation at a third stage. Fortunately for our success, this is readily possible in the surgical treatment of goiter. What I have on several occasions termed the many-stage operation, seems to me a most important factor of safety in the surgical treatment of exophthalmic goiter. Many years ago, Kocher advised preliminary ligation and others have followed his example. I was not aware that the surgical treatment of goiter had been divided into several minor stages at different times, varying from a few days to several weeks until I used this method, over three and a half years ago. During the past three years, I have operated in many desperate cases with ultimate satisfactory recovery. Many had hearts dilated to the axilla; at the beginning many were extremely anemic; nearly all of these had abumin and casts in the urine; persistent cough and diarrhea were present with a few; in several the heart's action was irregular, intermittent and feeble. All of these patients were treated by preliminary rest, tonic and hygienic measures. The operation itself was divided into many stages; in some, first, ligation of the superior thyroid on the least affected side; second, ligation of the artery on the side of greatest enlargement. Further treatment depends on the improvement after preliminary rest and ligation. In some the gland can be removed at once. In others the gland is simply exposed and the wound packed with sterile gauze. In these cases of worst risk, the fourth stage consists in removing the gland and again packing with gauze, and closing the wound at a fifth stage. The number of stages should be made as few as possible, but it is always better to keep within the limits of safety than to do too much. How far it is safe to go can be determined only by careful preliminary study of the case and a good deal of experience. It is certain that only a few patients in the most desperate condition are so ill that they cannot safely undergo a short skin incision and ligation of a superior thyroid vessel. This accomplished, the skin flap can be reflected in a few minutes, exposing the gland. If the sternohyoid and thyroid muscles are left undivided, no very troublesome adhesions are formed, after preliminary ligation. This is an improvement over my technic as reported a year ago when I was accustomed to divide the muscles and expose the gland. Sometimes after such division of the muscles when the patient's condition seemed to indicate considerable delay before completing the operation, adhesions became dense and troublesome. In several cases, I have left the gauze packed in place for a week or more before attempting closure as a fifth stage. In all cases the importance of a prolonged rest-cure is urged on the patients. They are given to understand that this is just as much a part of the treatment as the operation itself and unless they are willing to follow advice until a cure is obtained, operation has been refused. That many patients otherwise doomed to certain death can be rescued by the stage operation, I am thoroughly convinced. In my opinion, the two most important factors concerning the safety of the operation itself are the use of local anesthesia in the desperate cases and the many-stage operation; doing a little and getting out; carefully estimating what the patient is able to stand.

AUTHOR'S RESULTS

During the past eighteen months of my work at Ithaca and at Clifton Springs, Dr. Howard L. Prince, my associate, and I have performed 167 consecutive operations for exophthalmic goiter without loss of life (105 excisions and 62 ligations and partial operations). These were cases with unmistakable symptoms and it is, I believe, the largest number of operations for exophthalmic goiter yet reported without fatality. The cases have not been selected, the only patients refused operation being those in a desperate state who died medical deaths without surgical interference, in from twelve hours to three weeks from the time when they were seen and advised not to undergo operation. The results have come, I believe, more from the methods adopted, cooperative study of the probable resistance of each patient, and attention to many details, than from any special operative skill. That a later equal number of operations, including as many desperate cases, would result as fortunately is doubtful, but I believe the risks from operation itself are slight and mostly accidental. Kocher has shown from experience in about 5,000 operations, and several of his followers in series of several hundred cases, that the mortality rate need not exceed a small fraction of 1 per cent. in simple goiter. Personal experience convinces me that with attention to the details mentioned a 1 per cent. mortality (far less than for medical treatment in similar cases) is well within the range of possibility in exophthalmic goiter. This degree of safety is equaled in few other conditions of equal gravity.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. ROGERS AND TINKER

Dr. A. J. Ochsner, Chicago: Until recently our views regarding exophthalmic goiter have been based on a rather crude conception of hyperthyroidism, which we have received from Moebius. What this hyperthyroidism in itself represents we do not know, although the work that Dr. Rogers is doing will undoubtedly explain the elements of this condition. After we have Dr. Roger's analysis and that of many others who are working in this direction, our conception will undoubtedly be clear. Whether this can happen in the immediate future remains to be seen. There are many most acute, active and industrious observers who are working in this field.

Up to the present time we find all of the tissues of the body burdened with this hyperthyroid poison. It is a condition very much like poisoning with venom, which you can see pass over the patient. Occasionally a patient shows definite periods of poisoning. A period of excitement will be followed by an increase in the thyroid circulation, and within a few hours this patient will be almost overcome by the presence in his circulation of this substance which Dr. Rogers has partly analyzed, and which he will undoubtedly analyze completely.

So far as we were concerned up to the present time it was possible in some instances to reduce this hyperthyroidism by supplying the most favorable possible conditions of hygiene, rest and absence of excitement, and especial forms of nourishment. In other cases it was possible to prevent the formation of this substance by mechanically obstructing the blood-supply. In severe cases this was the first thing to do, to reduce as much as possible the blood-supply by ligating one or two or even three of the superior and inferior thyroid arteries and veins, so that the gland would have less material out of which to produce this poisonous substance. The next step was to remove a portion of the secreting glands, if we could determine what portion caused this hypersecretion, and if it seemed from the general condition of the patient that this could be done with safety. When we know more about the character of this secretion then we may be able to approach it from an entirely different side.

As regards the subject considered by Dr. Tinker, I would say that almost all of us who have operated in a large number of these cases considered our success to be due to this, that or the other feature, and after a while we dropped each of these features and our patients recovered precisely as rapidly and with precisely the same lack of danger as they did when we considered those the important elements in our success. There was a time when, following Kocher's method, almost everyone considered local anesthesia as the only safe means of performing this operation. There are several elements in the use of local anesthesia which are exceedingly valuable, namely, in the first place, you are compelled to pay closer attention to your operation when the patient is awake than when he is asleep. It is not possible to sit and think while you are trying to make out what to do. Again you must do the operation, if it is performed under local anesthesia, with the least possible amount of traumatism. I believe that any surgeon who tends to be violent in his operative procedures should operate under local anesthesia, because the patient will not submit to a violent operation, and the surgeon will thus be prevented from doing harm. In my own clinic I have repeatedly operated under local anesthesia, but only rarely during the past four or five years, because experience has shown that this does not increase the safety. The method that I have found safe and satisfactory consists in giving the patient ¼ gr. morphin hypodermically, and 1/100 gr. atropin one-half hour before the anesthesia is given. The patient is then thoroughly anesthetized with ether by the drop method, placing the patient in a horizontal position until fully anesthetized and then elevating the head by placing the patient in the inverted Trendelenburg position at an angle of 45 degrees, causing an anemia of the brain, which lasts throughout the operation. The atropin prevents the accumulation of mucus in the larynx and that does away, virtually, with any possibility of pneumonia. So that these patients do not have pneumonia after the use of the anesthetic. The morphin prevents the sensitiveness and reduces the amount of anesthetic required.

The heart is improved by the use of ether. I have never yet seen a case in which the heart was not better after the anesthetic than before; and being under the influence of this morphin for half an hour before the anesthetic is begun, the patient goes under the anesthetic without the slightest excitement. Thus we make use of the principle which our distinguished President brought out some years ago.

DR. JOHN ROGERS, New York: I wish to call attention to the comparative simplicity of these phenomena. They may all be referred to the thyroid alone or to the thyroid in connection with the associated glands. I must warn against operating on patients indiscriminately. Thyroidism can often be relieved by feeding substances not found in the thyroid. These preparations to which I have referred, which cannot be obtained commercially now, the Cornell Medical College will supply to you on request. There are many times when the use of the commercial thyroid is injurious; in fact, in the majority of cases it is injurious, on account of the chemical composition of the substance, as it does not contain all the normal ingredients of the gland.

In spite of what Dr. Ochsner has said, I must strongly advise against the use of ether. It is very easy under local anesthesia to make whatever division of vessels is necessary, or under nitrous oxid to remove whatever part of the thyroid you desire.

DR. MARTIN B. TINKER, Ithaca, N. Y.: I have for many years championed the use of local anesthesia for this work and for much other surgery. A final decision as to its value may safely be left to those men who have had surgical experience, and who will take the trouble to see the work done properly under local anesthesia and compare it with the work done under general anesthesia. Not one, but many men have been converted to the use of local anesthesia in these cases after seeing it properly employed.

I have had experience in doing the work and seeing it done under both methods; not that I have had a great deal of personal experience with ether, but I had to give it in my early experience for others. If any of you see the relative simplicity of the local anesthesia method, the comfort and the safety of your patients, many of them desperate cases, and are not convinced, then I have nothing further to say.

Protozoa.—Verworn in 1888 made the statement that protozoa seem to have been especially adapted by nature for the purposes of the physiologist, for here, in the single cell, are performed all of the functions which higher animals perform. —Calkins in *Science.*

THE PHENOLSULPHONEPHTHALEIN TEST FOR ESTIMATING RENAL FUNCTION *

J. T. GERAGHTY, M.D., AND L. G. ROWNTREE, M.D.
BALTIMORE

INTRODUCTION

In July, 1910,[1] we presented our original communication on the results obtained on our experimental and clinical studies of the functional activity of the kidneys by means of phenolsulphonephthalein. Some additional data were presented in subsequent papers.[2] The present communication is a summary of our experience with the test during the past two years,[3] and deals particularly with its value in relation to nephritis.

Phenolsulphonephthalein,[4] which was first prepared by Remsen, is a bright red crystalline powder somewhat soluble in water and alcohol, but readily soluble in the presence of alkalies. The drug, as determined by Abel and Rowntree, is non-toxic, excreted with extraordinary rapidity, and appearing in the urine normally within a few minutes of injection. In alkaline solution a brilliant red color is produced, which is ideally adapted for quantitative colorimetric estimations.

TECHNIC

Twenty minutes to half an hour before administering the test, the patient is given 300 to 400 c.c. of water in order to insure free urinary secretion, otherwise delayed time of appearance may be due to lack of secretion.

Under aseptic precautions a catheter is introduced into the bladder, and the bladder completely emptied. Noting the time, 1 c.c. of a carefully prepared solution of the phenolsulphonephthalein containing 6 mg. to the cubic centimeter is accurately administered subcutaneously, intramuscularly or intravenously by means of an accurately graduated syringe. (We have used the Record 2 c.c. syringe, which is graduated in fifths of a cubic centimeter.)

The urine is allowed to drain into a test-tube in which has been placed a drop of 25 per cent. sodium hydroxid solution, and the time of the appearance of the first faint pinkish tinge is noted.

In patients without urinary obstruction, the catheter is withdrawn at the time of the appearance of the drug in the urine, and the patient is instructed to void into a receptacle at the end of one hour, and into a second receptacle at the end of the second hour.

A rough estimate of the time of appearance can be made by having the patient void urine at frequent intervals, without the use of the catheter. In prostate cases it is wise to have the catheter in place until the end of the observation.

When a catheter is to be employed, it is well to previously have the patient under the influence of hexamethylenamin.

Sufficient sodium hydroxid (25 per cent.) is added to make the urine decidedly alkaline in order to elicit the maximum color. The color displayed in the acid urine is yellow or orange, and this immediately gives place to a brilliant purple-red color when the solution becomes alkaline. This solution is now placed in a liter measuring-flask and distilled water added to make accurately 1 liter. The solution is then thoroughly mixed, and a small filtered portion taken to compare with the standard which is used for all of these estimations.

[3] Detailed reports of our later studies will shortly appear.

[4] Am. Chem. Jour., vi, 280.

Recently the He[illegible], especially modified for use in [illegible] work, has been utilized. A standard alkaline solution, 6 gm. to a liter, is placed in the wedge-shaped cup. The urine collected is diluted to a liter and a small filtered portion poured into the rectangular cup. The wedge-shaped cup is now manipulated by means of the screw until the two sides of the color field are identical. The percentage on the scale is now noted. This instrument is much cheaper than the Duboscq and approximately accurate. Fairly accurate estimations, however, can be obtained by means of graduated cylinders—equal quantities of the standard solution and the diluted urine being used in separate cylinders, and the denser solution being diluted until the colors become identical. The amount of drug in the solution being known, the amount in the urine can be readily calculated.

When the collected urine has been made strongly alkaline, it is necessary to estimate the phthalein within a few hours, as the red color fades gradually under these conditions. When it is desirable or necessary to defer the estimation for some hours or days, it is better to make the urine distinctly acid, under which condition the phthalein remains unchanged. It should, of course, be made alkaline again when the estimation is made.

EXCRETION IN NORMAL INDIVIDUALS

The excretion has been studied in several hundred normal individuals. In our earlier work subcutaneous administration was used exclusively, the drug appearing in the urine in from five to eleven minutes, 38 to 60 per cent. (average 50 per cent.) being excreted in the first hour after its appearance in the urine, and 60 to 85 per cent. for two hours. In health the elimination is practically complete in two hours, only a trace being present during the third and fourth hours.

Recently intramuscular and intravenous injections have been employed. The time of appearance following the intramuscular administration is practically the same as that after the subcutaneous, but the output averages 5 to 10 per cent. more for the first hour. Following the intravenous injection, the drug normally appears in from three to five minutes, and from 35 to 45 per cent. of the drug is eliminated in the first fifteen minutes, 50 to 65 per cent. in the first half hour, and 63 to 80 per cent. during the first hour. This rapidity of the excretion, following intravenous administration, is exceedingly striking, and when this method is employed, observations for a quarter-hour or half-hour period only should be employed. For general use, however, we advocate the lumbar intramuscular method (the latter particularly when edema is present), as the technic involved is much simpler and the results obtained are reliable. The technic of the test is exceedingly simple. The injection is given, time of appearance noted, and collection of urine made for one or two hours. To each sample sufficient sodium hydrate is added to insure alkalinity and maximum intensity of color; then the urine is diluted to 1 liter, a small amount is filtered, the reading made, and the percentage of drug excreted is calculated.

INFLUENCE OF AMOUNT OF URINARY SECRETION

The excretion of the drug does not run parallel to the excretion of urine. It is immaterial as far as the excretion of the drug is concerned whether the urinary output is 50, 200, 400 or 500 c.c. Similarly, the output does not seem to be much influenced by the previous administration of the different diuretics. Experimentally, on animals it was found that those diuretics (caffein, urea, dextrose, phloridzin, calomel) which are thought to exert a stimulating influence on the cells of the renal tubules, slightly increase the phthalein output, whereas those diuretics (hypertonic sodium chlorid, potassium nitrate and digitalis) which act entirely by mechanical factors as by changes in osmotic tension, or changes in blood-pressure, slightly decrease or cause no change in the excretion of phthalein. No definite influence was noted in man, following the dosage usually employed for diuresis, one-hour estimations being made.

THE STUDY OF NEPHRITIS

Heretofore, functional tests have not been considered of any great value to the clinician in relation to nephritis. In fact, hyperpermeability to methylene blue, indigo-carmin and rosanilin has been shown to exist in acute and in chronic parenchymatous nephritis, while, on the other hand, decreased permeability with slow appearance and prolonged excretion has been demonstrated in the chronic interstitial variety.

ACUTE NEPHRITIS

An opportunity to study only five cases of acute nephritis has presented itself.

While no conclusions can be drawn from five cases, it is sugestive that in none of them was there increased permeability, but that, on the contrary, the permeability was markedly decreased when the condition was considered clinically grave.

CHRONIC PARENCHYMATOUS NEPHRITIS

In all, twenty-one cases belonging to the clinical type of parenchymatous nephritis have been studied. These cases represent different grades of severity and the duration of the disease varies from a few weeks to seven years.

In two very mild cases of short duration showing only slight edema, with albumin and casts, but with a normal urinary output, the time of appearance of the drug and the amount excreted was normal. In one of these cases the time of appearance was eight minutes and the output 52.5 per cent. for one hour. The second patient was a student who considered himself perfectly well, but in whose urine albumin and casts were discovered by chance. On close inspection, a slight edema about the eyes was detected. No other evidence or suggestion of the disease could be found. In this instance 53 per cent. for the first hour and 8.6 per cent. for the second hour was excreted following subcutaneous injection.

In cases of longer standing, or those in which the disease is of ordinary severity, the time of appearance has always been delayed slightly (ten to twenty-five minutes) and the amount excreted is definitely below normal.

In the most severe grades of chronic parenchymatous nephritis, or those in which the disease is of long standing and associated with secondary sclerotic changes, the output is reduced very markedly, and in some instances no trace of the drug can be found in the urine. Here, also as in the interstitial type, the absolute failure of excretion, or the excretion of a mere trace, has been followed within a short time by death from renal failure.

Although the number of cases of chronic parenchymatous nephritis has not been very large, sufficient data have been collected to indicate that the test is of decided value in revealing the functional efficiency of the kidney in this condition. In the mild cases very little disturbance of function is indicated, and it may be impossible from the test alone to differentiate this condition from albuminuria. When there is a marked decrease in the phthalein output, marked renal changes are present, and when only excreted in traces, or not at all, a grave prognosis should be given, though no signs of uremia exist.

CHRONIC INTERSTITIAL NEPHRITIS

Twenty-two cases of the type clinically classed as chronic interstitial nephritis have been under observation. In many of these cases, previous to the administration of the phthalein test, no accurate idea of the degree of involvement of the renal function could be ascertained even after the most careful clinical study. The phthalein test has proved itself of immense value in revealing the degree of destruction of the renal substance, and has demonstrated itself to be of extreme importance from the standpoint of both diagnosis and prognosis.

In most of the cases of this series the time of appearance has been markedly delayed and the output of phthalein markedly decreased; where the output is lowest, the delay in appearance is most pronounced. The time of appearance, however, is not so important as the amount of excretion.

The following case is cited as an example of the accuracy of the test in revealing the true renal condition:

CASE 1.—*Patient.*—S. B. G., aged 55, surgical No. 25,174, was admitted Dec. 21, 1909, complaining of difficulty and frequent urination. These urinary symptoms were dependent on prostatic enlargement, the residual urine amounting to 440 c.c.

Examination.—Patient was apparently in good physical condition, well nourished, but slightly anemic. Urine slightly cloudy, acid, specific gravity 1,010, no sugar, slight trace of albumin and no casts. Urinary output 2,000 c.c. in twenty-four hours, urea ranging from 20 to 30 gm. for twenty-four hours. The phthalein test was given, a faint trace appearing in forty minutes, and at no time was more than the merest trace detected.

Repeated subsequent tests yielded always the same result. One week after administration the patient began to exhibit signs of uremia, which gradually increased until deep coma ended in death.

Autopsy.—Both kidneys presented marked atrophy, neither organ weighing one-third of normal, a severe grade of interstitial nephritis being present.

This case is of particular interest because of the fact that the urinary output, the urea, the total solids and the total nitrogen were normal and casts were also absent.

In the following case the diagnosis was exceedingly obscure until the evidence brought forward by the test was added. Before the administration of the test, nephritis was only one of many possibilities entertained.

CASE 2.—*Patient.*—Mrs. O., aged 47, admitted March 23, 1911, noted fatigue and dyspnea on slight exertion, together with slight edema of lower extremities. In December nausea and vomiting developed and have been present almost constantly since.

Examination.—The patient was poorly nourished and showed marked anemia; no edema of extremities. Urine was pale yellow, specific gravity 1,011, albumin, a trace; no casts on repeated examinations. Blood-pressure was 135. Eye-grounds were negative. Although nauseated, the patient was mentally bright and seemed in no immediate danger.

The phthalein test showed no output in three hours. Two days later the patient became irrational, dying within forty-eight hours in uremic convulsions. No autopsy was obtained.

The following case shows even more strikingly the ability of the phthalein test to reveal the presence of nephritis in the absence of any definite clinical evidence.

CASE 3.—*Patient.*—L. G., aged 12, admitted March 27, 1911, presented an interesting case of diabetes insipidus. The past history contained nothing of importance, except that large quantities of urine had been voided for some time and he experienced marked thirst.

Examination.—He was well nourished, not anemic, and apparently a normal-looking boy. His blood-pressure ranged from 80 to 90 m.m. Hg. Some thickening of the radial arteries was noted. No eye changes. The urine on admission was large in amount, 2,000 to 2,500 c.c., clear, specific gravity 1,005 to 1,010; no albumin, no casts. At this time no suspicion of nephritis was entertained. The phthalein test, performed March 28, showed an output of only 7 per cent. for two hours. Three days later only 2 per cent. was excreted. With the exception of the phthalein findings, absolutely no evidence of nephritis was present at this date. A week later the patient developed headache and a trace of albumin appeared in the urine. He rapidly became uremic and died April 9, 1911.

Autopsy.—A most intense grade of chronic interstitial nephritis was present, with almost complete disappearance of the cortex. A slight grade of acute nephritis was superimposed.

Chronic nephritis can exist over a long period without recognition, and may even exist in the absence of albumin and casts in the urine. The following is another case illustrating the presence of nephritis in the absence of positive clinical proof, and also the value of the phthalein test in revealing its existence.

CASE 4.—*History.*—F. G., aged 71, who had had six previous admissions for malaria, febricula, acute rheumatic fever and arthritis deformans during the last five years, was again admitted Nov. 7, 1910, for vertigo and attacks of loss of consciousness. Numerous urinalyses during these admissions failed to demonstrate any anomaly, except a trace of albumin at one single examination. An advanced arteriosclerosis and high blood-pressure were recorded on previous admissions.

Examination.—Urine was pale, 1,012, acid, albumin, occasional trace, no casts. Phthalein examination showed an output of only 5 per cent. for the first hour and 10 per cent. for the second, indicating a severe grade of nephritis.

Shortly afterward patient died of bronchopneumonia.

Autopsy.—Atrophy of the right kidney as the result of an old thrombosis of right renal artery, with chronic diffuse nephritis on the left side, small granular kidney.

UREMIA

In twenty-one cases under study, uremia has been present. Of this number, in fourteen uremia was grave; the patients exhibited nausea, vomiting, drowsiness or coma, and in several instances convulsions. In the remaining seven, mild symptoms only were present and had persisted over prolonged periods. Nine of the fourteen patients with grave uremia died during the attack. In all of these cases the phthalein elimination was zero or a faint trace only for two hours.

In two of the five patients recovering from their uremia, the output was 20 per cent., the uremia being the result of an acute exacerbation of a chronic nephritis. In two the output was 14 per cent.; in both of these the uremia was precipitated by a double pyelonephritis. The fifth case was one of acute exacerbation of chronic pyelonephritis in a man previously having had a nephrectomy. This last patient has greatly improved, and at present has a two-hour excretion of 13 per cent.

In the seven mild cases, exhibiting slight but persisting symptoms of uremia, the excretion respectively was as follows: 10 per cent. in one, 7 per cent. in three cases, a trace in two, 2 per cent. in the other for two hours. Five of these patients died within three months of the performance of the test. Those living are still exhibiting evidences of chronic uremia, four months having intervened in one instance.

Of four patients not exhibting uremia at the time of the test, but in which the phthalein output was below 8 per cent. for two hours, one excreting 6 per cent. died within two months, another within three months, and the other two are still living, in one two months, and in the other three weeks intervening, but both are exhibiting evidence of chronic uremia.

THE STUDY OF CARDIAC AND CARDIORENAL CASES

An attempt has been made to differentiate by means of this test between those cardiac cases with broken compensation or with passive congestion associated with the presence of albumin and casts in the urine and those cases in which cardiac insufficiency is associated with varying grades of true nephritis. In this connection thirty-three cases have been studied. From this study there appears to be no doubt but that decrease in function accompanies marked passive congestion of the kidneys in the absence of any true nephritis. As the cardiac condition improves, however, the passive congestion becoming less marked and edema subsiding, the output of phthalein increases, and in one case rose from 16 per cent. to normal in the course of one week, the patient in the meantime losing 70 pounds in weight with the disappearance of a general anasarca. We feel that the phthalein test will prove of value in determining what degree of renal efficiency exists in this class of disease, and subsequently with improvement in the cardiac condition and the disappearance of edema, a continued low phthalein excretion will indicate with considerable certainty the presence of permanent organic changes in the kidney. We feel, however, that a much larger series should be studied clinically and at autopsy before very definite conclusions can be drawn.

MISCELLANEOUS CASES

A large number of miscellaneous medical diseases have also been studied from the standpoint of phthalein excretion, among the number being ten cases of lobar pneumonia. In pneumonia the output is little if any decreased, and does not run parallel with the chlorid excretion. Three cases of persistent albuminuria have shown a normal output. In no disease other than renal, so far studied, has a marked reduction of the phthalein excretion been encountered.

THE RELATION OF PHTHALEIN OUTPUT TO BLOOD-PRESSURE, TO CHANGES IN THE EYE-GROUNDS AND TO THE BLOOD-PICTURE

In the majority of cases of chronic nephritis in which the blood-pressure has been high, the phthalein elimination has been markedly decreased, but no exact parallelism exists, inasmuch as not a few instances have been encountered in which the systolic pressure has been over 200 mm. Hg; and the phthalein output one-half of normal, while on the other hand there have been instances in which the blood-pressure has been normal while the phthalein output has been zero or nearly so, the patients shortly after dying in uremia. While a high blood-pressure, when present, is considered of diagnostic and prognostic value taken in conjunction with other clinical data, yet many patients died of renal insufficiency and exhibited a blood-pressure which was normal or practically so. Nor is the blood-pressure, even when high, increased in inverse proportion to the decrease in renal function.

While in some instances marked changes in the eye-grounds, choked disk, tortuous vessels, hemorrhages, etc., have been present coincident with a very low phthalein output, in many cases, even of the most advanced and even fatal nephritis, no changes whatever in the eye-grounds could be detected, the patient at the same time failing to eliminate the phthalein.

Moderate or rather severe grades of secondary anemia in the absence of disease of the kidneys can be present without any diminution in the phthalein elimination; for instance, two patients, one with 2,500,000 red cells, and hemoglobin 30 per cent., the other with hemoglobin 30 per cent., eliminated 61 and 57 per cent. for two hours, respectively.

VALUE OF TEST FROM A SURGICAL STANDPOINT

Through the encouragement of Dr. Hugh H. Young we have been enabled to study the phthalein excretion in a large series of cases of urinary obstruction, in order to determine the value of the test in revealing the functional capacity of the kidney in these cases. This is a consideration of grave importance in this connection, since the development of uremia or renal failure has been responsible for a great part of the mortality following surgical interference.

As a result of obstruction in the lower urinary tract, pathologic changes may occur in the ureters and kidneys, dilatation of the ureters, varying grades of hydronephrosis, and as a result of the continued high pressure, atrophy of the parenchyma of the kidney. Not infrequently, infection occurs with the development of a pyelitis, a diffuse or localized pyelonephritis, or pyonephrosis. The occurrence of these complications is often difficult of recognition, and is often overlooked, particularly in the absence of symptoms of renal inadequacy. A large proportion of these cases of urinary obstruction have cystitis associated with albuminuria. The presence of casts in the urine is no contra-indication to operation. The urinary output may be normal, also the urea and total solids, and yet the patient may be on the verge of renal failure and disastrous results may follow surgical interference.

The test has been used in 100 cases of urinary obstruction, mostly cases of prostatic hypertrophy. The technic involved in these cases necessitates the use of a catheter, otherwise it does not differ from that described above.

In the majority of cases, the test indicates a more or less degree of renal impairment, and taken in conjunction with the clinical condition it is of more value than the study of urine output, total solids, total nitrogen, and urea estimations combined.

A marked decrease in the amount excreted invariably means severe derangement of renal function, which may be of either a temporary or permanent character. Under such conditions one should proceed with extreme caution, and no surgical intervention should be attempted without further study together with preliminary treatment. Under this regime, repeated functional tests will demonstrate eventually the nature of the derangement, for in true interstitial nephritis the output will continue low, whereas if the derangement is purely functional or secondary to pyelonephritis, usually improvement will follow as a result of the treatment and will be indicated by a decrease in the time of appearance of the drug and simultaneously an increase in the amount eliminated.

The functional derangement due to infection in these cases is a much more dangerous condition than is the presence of even a fairly advanced condition of interstitial nephritis. The use of the test enables one to select the most favorable time for operation. In cases exhibiting a continued suspiciously low output, the use of nitrous oxid gas, or spinal anesthesia, is suggested as preferable to ether in order to protect the kidneys. When only a trace of the drug continues to be excreted, prostatectomy should not be attempted, even though the patient presents no evidence of uremia.

In our original paper we stated that a dropping phthalein output was a contra-indication to operation except in cases of necessity. This decrease in function usually means some change in the renal condition and in most of our cases it has been caused by the development of a pyelonephritis or an exacerbation of an old process. It is obviously wise to wait until the kidneys have recovered from this acute shock before subjecting them to further injury through operation.

The test can be used to equal advantage preliminary to any surgical procedure, when it is deemed important to know the true functional capacity of the kidneys.

TECHNIC OF THE PHTHALEIN TEST AS APPLIED TO ESTIMATION OF THE FUNCTION OF THE INDIVIDUAL KIDNEY

Functional tests have already demonstrated their value in this connection. But they have at most been able to determine only the relative working capacity of each kidney and have shed very little light on the absolute functional capacity of each organ.

The phthalein test in association with ureteral catheterization has been used in seventy cases of unilateral or bilateral disease.

Twenty minutes previous to examination 600 to 800 c.c. of water are given to the patient in order to insure a free flow of urine. The ureters are then catheterized.

As it is essential to collect all the urine secreted by each kidney during a definite period of time, in order to do accurate quantitative work, a form of ureteral catheter especially devised for this purpose has been used. The flute end catheter of Albarran, No. 6, or preferably No. 7, has been found to be most satisfactory. The catheters which have only side openings and no end opening cannot be depended on for this purpose.

The catheters are passed up into the ureters to a distance of four inches. The cystoscope is then withdrawn, leaving the ureteral catheters in position. A small ureteral catheter is now passed into the bladder and the bladder thoroughly emptied, so that leakage, should it occur, can be detected.

The time of injection is recorded, as is also the time of the appearance of the drug on each side. Starting from the time of appearance, the collection is then continued for one hour following subcutaneous or intramuscular injection. The amount of drug in each specimen is then estimated by the technic described above.

RESULTS OBTAINED WITH THE PHTHALEIN TEST

In normal cases the time of the appearance of the drug from the two sides has been almost always the same, and in the majority of cases this has been five to ten minutes following subcutaneous and three to five minutes following intravenous. The time, of course, will vary somewhat with the rate of urinary secretion. Normally the amount excreted by each kidney will be practically the same. The series of cases studied include tubercular or pyogenic infection, unilateral or bilateral, calculi, hydronephrosis, hypernephromata, etc.[5]

UNILATERAL OR BILATERAL SURGICAL DISEASE OF THE KIDNEY

It has been demonstrated that the time of appearance and the percentage of output is practically the same for the two healthy kidneys. When one kidney only is diseased, the time of the appearance of the drug is delayed on the diseased side, and the amount excreted is not only relatively but absolutely decreased. The amount of delay in the time of appearance is comparatively of little value. Reliance is only to be placed on the quantity excreted during a period of one-half or one hour, depending on the method of administration.

Although in the majority of these cases of unilateral disease the combined output is equal to that of two normal kidneys, the greater part of the excretion is shown to be performed by the healthy kidney. In proportion to the decrease in function on the diseased side, approximately there is a proportionate increase in the function on the healthy side. In such cases following nephrectomy the remaining kidney eliminates after the lapse of two or three weeks an amount of drug which is normally excreted by two healthy kidneys. In all cases studied, the output from the remaining kidney has been greater than the combined output from two kidneys prior to operation.

In bilateral disease it has been found possible to determine the individual function (absolute or relative) of each kidney. It is in this class of cases particularly that the shortcomings of other functional tests have been most apparent, as one kidney may be doing twice or three times the amount of work of the opposite kidney, and still be unable to assume the additional work of the other kidney. It may be doing the major part of the work at the expense of all, or nearly all, of its reserve power, but the phthalein test determines whether the kidney has a functional capacity which is normal, less than or greater than normal and to what degree. In three cases of double renal tuberculosis, in which the amount of pus from each side was practically the same, the test permitted it to be determined that one kidney in each instance had a function greatly in excess of the other, indeed sufficient functional capacity to allow of successful nephrectomy, marked improvement in general condition occurring subsequently in each case.

In six cases out of seventy we have found that the catheters caused some inhibition of function, as was also observed by Keyes Jr. and Stevens. This influence can readily be estimated by taking the total function either before or after catheterization.

The test has been used by us simultaneously with cryoscopy, phloridzin, indigo-carmin, and the polyurea test of Albarran. No particular advantage was added by combining with one or all.

CONCLUSIONS

1. The phenolsulphonephthalein as used by us has many advantages over all other functional tests thus far proposed.

2. Phenolsulphonephthalein itself is better adapted for use as a functional test than any other drug previously employed for the same purpose on account of its

---

[5] The details concerning forty-two of these cases are considered in previous communications, Tr. Am. Assn., G.-U. Surg., 1911, and Ann. d. mal. d. org. génito-urin., February and March, 1911.

early appearance in the urine and the rapidity and completeness of its elimination by the kidney and the reliance to be placed on its findings.

3. The method of quantitative estimation of the amount of drug excreted is simple and exceedingly accurate.

4. It is of immense value from a diagnostic and prognostic standpoint in nephritis, inasmuch as it reveals the degree of functional derangement in nephritis whether of the acute or chronic variety.

5. In the cardiorenal cases the test may prove of value in determining to what degree renal insufficiency is responsible for the clinical picture presented.

6. The test has proved of value not only in diagnosing uremia from conditions simulating it, but has also successfully indicated that uremia was impending when no clinical evidence of its existence at the time was present.

7. The test has proved of great value in revealing the true renal condition in cases of urinary obstruction. It is here of more value than the urinary output of total solids, urea or total nitrogen and enables the surgeon to select a time for operation when the kidneys are in their most favorable functional condition. The improvement in the renal condition in cases of urinary obstruction, following the institution of preliminary drainage, is strikingly indicated by this test.

8. In unilateral and bilateral kidney disease the absolute amount of work done by each kidney, as well as the relative proportion, can be determined when the urines are obtained separately. We do not feel that this is always mathematically accurate, but in our series it has indicated the functional capacity to a degree not attained by any other test.

It is with the greatest pleasure that we thank Dr. Young for his early and continued interest in this work, and for the generous supply of clinical material referred to us by him, by Dr. Barker, Dr. Thayer and the other members of the hospital medical staff for the opportunity of studying the cardiac and nephritic cases, and Dr. F. W. Hobleman for his valuable assistance in carrying on the work, and Dr. Dunning of Hynson, Westcott, for kindly furnishing us with the phenol sulphonephthalein used throughout this study.

SOME OBJECTIONS TO THE USE OF ALUM BAKING-POWDER*

WILLIAM J. GIES, Ph.D.
NEW YORK

I. INTRODUCTION

During a period of about seven years I have occasionally conducted experiments on the effects of aluminum salts. These studies have convinced me that the use in food of alum or any other aluminum compound is a dangerous practice. That the aluminum ion is very toxic is well known. That "aluminized" food yields soluble aluminum compounds to gastric juice (and stomach contents) has been demonstrated. That such soluble aluminum is in part absorbed and carried to all parts of the body by the blood can no longer be doubted. That the organism can "tolerate" such treatment without suffering harmful consequences has not been shown. It is believed that the facts in this paper will give emphasis to my conviction that aluminum should be excluded from food.[1]

II. EXPERIMENTS BY HOUSE AND GIES ON THE EFFECTS OF ALUMINUM COMPOUNDS ON THE GROWTH OF SEEDLINGS

Several years ago, in collaboration with House, I published the general results of a study of the influence of aluminum compounds on typical seedlings. The essential facts in that connection were summarized in the appended statement and accompanying table (Table 1).[2]

> Although aluminum compounds appear to exist in small proportions in many plants, and occur in traces in some animals, relatively little has been learned regarding the biological effects and significance of aluminum. The authors have begun a series of studies in this connection, the first of which has been an investigation of the influence of aluminum on lupin seedlings. The methods described by True and Gies[3] were used, and the following compounds were taken: aluminum sulphate, aluminum nitrate, aluminum chlorid, aluminum-sodium chlorid, potassium alum, and ammonium alum. The accompanying table (1) presents some of the more significant results, which represent the average of very many observations for periods of forty-eight to seventy-two hours.
>
> In nearly all cases, in these experiments, little or no effect was produced at a concentration of $m/65{,}536$ [i. e., per liter the molecular weight in grams divided by 65,536]. In concentrations greater than $m/65{,}536$, growth usually was markedly inhibited. In concentrations less than $m/65{,}536$ and down to $m/1{,}048{,}576$, or $m/2{,}097{,}152$, growth was stimulated as a rule.

TABLE 1.—DATA SHOWING THE COMPARATIVE EFFECTS OF ALUMINUM COMPOUNDS ON THE GROWTH OF LUPIN SEEDLINGS

Aluminum Compound	Greatest Molecular Concentration that Permitted Slight Initial Growth	Least Molecular Concentration in Which There Was No Growth After 24 Hours	Greatest Molecular Concentration in Which Growth Was Equal to that in the Pure Water Control	Molecular Concentration in Which Initial Stimulation Took Place	Molecular Concentration in Which the Maximum Stimulation Occurred
	m/x	m/x	m/x	m/x	m/x
$Al_2(SO_4)_3$ ...	8,192	16,384	65,536	131,072	1,048,576[1]
$Al(NO_3)_3$	1,024	16,384	65,536	131,072	1,048,576
$AlCl_3$........	2,048[2]	2,048[2]	65,536[3]	131,072[4]	131,072
$AlCl_3NaCl$ ...	16,384	32,768	65,536	131,072	131,072
$KAl(SO_4)_2$ ...	1,024	4,096	32,768	65,536	131,072 524,288
$NH_4Al(SO_4)_2$..	8,192	16,384	131,072	262;144	524,288

1. The concentration of aluminum in a $m/1{,}048{,}576$ $AlCl_3$ solution is 0.000,0[illegible] per cent.
2. The concentration of aluminum in a $m/2{,}048$ $AlCl_3$ solution is 0.001,3 per cent.
3. The concentration of aluminum in a $m/65{,}536$ $AlCl_3$ solution is 0.000,04 per cent.
4. About midway between $m/131{,}072$ and $m/65{,}536$. The concentration of aluminum in a $m/131{,}072$ $AlCl_3$ solution is 0.000,02 per cent.

These results showed clearly that compounds of aluminum, such as the chlorid, even when present in very minute proportions, are strong protoplasmic poisons and very toxic to growing plants.

III. MALLET'S EXPERIMENTS ON THE SOLUBILITY, IN GASTRIC CONTENTS, OF ALUMINUM COMPOUNDS CONTAINED IN BREAD MADE WITH ALUM BAKING-POWDER

Two years ago I was asked by Prof. J. W. Mallet to examine and discuss some results of Professor Mallet's investigation on the "solubility, in the stomach, of aluminum compounds contained in bread made with alum baking-powder." These results were summarized in the appended personal statement by Professor Mallet (dated Aug. 27, 1909):

---

* From the Laboratory of Biological Chemistry of Columbia University, at the College of Physicians and Surgeons, New York.

[1] This paper is purposely restricted to a discussion of the work of the author and his collaborators.

[3] True and rey Botanical Club, 1903, xxx, 390. Also Biochemical Researches 1903, i (reprint

EXPERIMENTS PERFORMED BY PROFESSOR MALLET

The baking-powder used was of the "Bob White" brand—a "straight alum" powder—and was purchased in the open market. After addition of water the reaction was slightly alkaline. The flour selected was of choice quality for family use, prepared by the roller process. Bread was made with

	Gm.
Flour[4]	550
Common salt	8
White sugar	5
Baking powder (2 heaping teaspoonfuls)	16
Water	231

Great care was taken to secure uniform mixture of the solid materials by repeated siftings before water was added, and the dough was very thoroughly kneaded. The quantity of water stated is that remaining in the baked bread as eaten, allowance being made for the carbon dioxid gas expelled. The bread was baked as a batch of rolls to a light yellowish-brown crust. The porosity was uniform and satisfactory. The bread was palatable, notwithstanding the omission of any shortening ingredient.

Three persons were selected as subjects for experiment, viz.:
A.—J. N., white, male, aged 21. In normal health and condition.
B.—L. B., white, male, aged 21. In normal health and condition.
C.—W., Negro, male, aged 23. In normal health and condition.
Each of these subjects, having eaten nothing since the previous evening, ate in the morning a portion of the specially prepared bread, taking with it a limited quantity of water, avoiding great dilution with the latter.

A took about 128 gm. of bread and 175 c.c. of water.
B took about 85 gm. of bread and 175 c.c. of water.
C took about 171 gm. of bread and 325 c.c. of water.

An hour after eating, the contents of the stomach were in each case withdrawn by means of a stomach-tube, the turbid liquid obtained measuring:

In the case of A	156 c.c.
In the case of B	182 c.c.
In the case of C	197 c.c.

This turbid material was at once carefully filtered through muslin and then through paper, until a clear liquid was obtained. The filtration was slow, and the residue was lightly washed with a small quantity of water. The reaction of the liquid was in all three cases markedly acid.

The whole of the filtrate was in each case evaporated to dryness in a platinum dish over a water-bath, the dry residue carefully incinerated in the same dish, and the ash fused with sodium carbonate and a minute quantity of sodium nitrate, to destroy the last traces of organic matter. The fused residue was dissolved by nitric acid, the phosphoric acid radical removed by ammonium molybdate, and aluminum hydroxid precipitated by ammonia. The precipitate was again dissolved by nitric acid, again thrown down by ammonia, treated with pure sodium hydroxid to separate iron, once more precipi- by ammonium chlorid, thoroughly washed, dried, ignited and weighed. All parts of the process involving the use of heat were carried out in platinum vessels. In this way there was recovered from the contents of the stomach:

In the case of A	21 mg. of alumina (Al_2O_3)
In the case of B	23 mg. of alumina (Al_2O_3)
In the case of C	13 mg. of alumina (Al_2O_3)

In each case of alumina, after weighing, was fused with sodium carbonate, dissolved by hydrochloric acid, reprecipitated as hydroxid by ammonia, and fully identified by the use of all the chief tests for aluminum in its compounds.

Assuming the baking-powder to have been uniform in composition and to have been uniformly distributed in the bread, the three subjects had swallowed aluminum in the following amounts:

In the case of A	107 mg. of Al_2O_3
In the case of B	71 mg. of Al_2O_3
In the case of C	143 mg. of Al_2O_3

and hence of this there was recovered in solution from the portion of the stomach contents obtained:

In the case of A	19.6 per cent.
In the case of B	32.4 per cent.
In the case of C	9.1 per cent.

PROFESSOR MALLET'S CONCLUSIONS

The differences between these figures are not surprising in view of the unknown and variable quantities of gastric juice secreted in a given time, its variable degree of acidity, and the different proportions of diluting water. It will be seen that the smallest amount of aluminum—both absolute and in proportion to the amount swallowed—was recovered from the contents of the stomach of subject C, who ate most bread and took the largest absolute amount of water with it. It is to be borne in mind that not the whole, but only a part, of the contents of the stomach was in each case removed by the tube, and that hence the quantity of aluminum recovered in soluble form represents but a part of that which was actually dissolved.

The general result is plainly apparent, that a part, and no inconsiderable part, of the aluminum in the ingested bread made with alum baking powder was, under the action of the gastric juice, present in dissolved form in the stomach of each of the subjects of the experiments.

THE PRESENT WRITER'S OPINION OF PROFESSOR MALLET'S EXPERIMENTS AND OF THE SIGNIFICANCE OF THEIR RESULTS

In response to the request for an opinion regarding the possibly harmful effects of aluminum in the proportions (in gastric contents) that occurred in the experiments described above, I wrote in this connection to Professor Mallet as follows (Oct. 11, 1909):

The results given in your statement show clearly that well-baked bread, made with an alum baking-powder, contains aluminum in a form that will yield a surprisingly large proportion of a soluble aluminum compound or compounds to human gastric juice under normal conditions in the stomach. In one of your experiments, as much as 32.4 per cent. of the amount of aluminum introduced with the ingested bread was found in 182 c.c. of gastric contents removed "an hour after eating"—which volume was not, of course, the entire volume in the stomach at the time, to say nothing of prior natural intermittent removals of partly digested matter into the intestine. These facts suggest that in many instances more than one-third of the aluminum in the ingested portion of such bread may occur, at a time, in a *soluble* form in the digestive contents of the stomach. These data being before one—and your determination of them is conclusive assurance of their accuracy—what may be said regarding the "physiologic effects" of the aluminum that thus appears in the gastric juice in dissolved form?

I believe that aluminum, if present in the stomach, day after day, in dissolved form in such proportions would tend to modify unfavorably the gastric secretory and digestive processes. There would be repeated attacks on the mucous membrane, especially through the astringent and protein-precipitating properties of the dissolved aluminum. The associated presence of much protein material would tend to diminish such action, however, by causing the production of less toxic forms of *combined* aluminum.

I am satisfied that people with "poor digestions" would be influenced ultimately to their further disadvantage, as a rule, by meals usually containing aluminized bread. It is true that multitudes are able to withstand the deleterious influence of various poisonous substances, even for long periods, without exhibiting *distinguishable* detriment. Such seeming lack of direct harmful influence, however, is often insidiously mislead-

---

[4] The flour used in these experiments was examined for aluminum and yielded in the ash the equivalent of less than 1 mg. of Al_2O_3 for the largest quantity of bread eaten by any of the subjects.

appended personal statement by Professor Mallet (dated Aug. 27, 1909):

EXPERIMENTS PERFORMED BY PROFESSOR MALLET

The baking-powder used was of the "Bob White" brand—a "straight alum" powder—and was purchased in the open market. After addition of water the reaction was slightly alkaline. The flour selected was of choice quality for family use, prepared by the roller process. Bread was made with

	Gm.
Flour[4]	550
Common salt	8
White sugar	5
Baking powder (2 heaping teaspoonfuls)	16
Water	231

Great care was taken to secure uniform mixture of the solid materials by repeated siftings before water was added, and the dough was very thoroughly kneaded. The quantity of water stated is that remaining in the baked bread as eaten, allowance being made for the carbon dioxid gas expelled. The bread was baked as a batch of rolls to a light yellowish-brown crust. The porosity was uniform and satisfactory. The bread was palatable, notwithstanding the omission of any shortening ingredient.

A.—J. N., white, male, aged 21. In normal health and condition.
B.—L. B., white, male, aged 21. In normal health and condition.
C.—W., Negro, male, aged 23. In normal health and condition.
Each of these subjects, having eaten nothing since the previous evening, ate in the morning a portion of the specially prepared bread, taking with it a limited quantity of water, avoiding great dilution with the latter.

A took about 128 gm. of bread and 175 c.c. of water.
B took about 85 gm. of bread and 175 c.c. of water.
C took about 171 gm. of bread and 325 c.c. of water.

An hour after eating, the contents of the stomach were in each case withdrawn by means of a stomach-tube, the turbid liquid obtained measuring:

In the case of A	156 c.c.
In the case of B	182 c.c.
In the case of C	197 c.c.

This turbid material was at once carefully filtered through muslin and then through paper, until a clear liquid was obtained. The filtration was slow, and the residue was lightly washed with a small quantity of water. The reaction of the liquid was in all three cases markedly acid.

The whole of the filtrate was in each case evaporated to dryness in a platinum dish over a water-bath, the dry residue carefully incinerated in the same dish, and the ash fused with sodium carbonate and a minute quantity of sodium nitrate, to destroy the last traces of organic matter. The fused residue was dissolved by nitric acid, the phosphoric acid radical removed by ammonium molybdate, and aluminum hydroxid precipitated by ammonia. The precipitate was again dissolved by nitric acid, again thrown down by ammonia, treated with pure sodium hydroxid to separate iron, once more precipi- by ammonium chlorid, thoroughly washed, dried, ignited and weighed. All parts of the process involving the use of heat were carried out in platinum vessels. In this way there was recovered from the contents of the stomach:

In the case of A	21 mg. of alumina (Al_2O_3)
In the case of B	23 mg. of alumina (Al_2O_3)
In the case of C	13 mg. of alumina (Al_2O_3)

In each case of alumina, after weighing, was fused with sodium carbonate, dissolved by hydrochloric acid, reprecipitated as hydroxid by ammonia, and fully identified by the use of all the chief tests for aluminum in its compounds.

Assuming the baking-powder to have been uniform in composition and to have been uniformly distributed in the bread, the three subjects had swallowed aluminum in the following amounts:

In the case of A	107 mg. of Al_2O_3
In the case of B	71 mg. of Al_2O_3
In the case of C	143 mg. of Al_2O_3

and hence of this there was recovered in solution from the portion of the stomach contents obtained:

In the case of A	19.6 per cent.
In the case of B	32.4 per cent.
In the case of C	9.1 per cent.

PROFESSOR MALLET'S CONCLUSIONS

The differences between these figures are not surprising in view of the unknown and variable quantities of gastric juice secreted in a given time, its variable degree of acidity, and the different proportions of diluting water. It will be seen that the smallest amount of aluminum—both absolute and in proportion to the amount swallowed—was recovered from the contents of the stomach of subject C, who ate most bread and took the largest absolute amount of water with it. It is to be borne in mind that not the whole, but only a part, of the contents of the stomach was in each case removed by the tube, and that hence the quantity of aluminum recovered in soluble form represents but a part of that which was actually dissolved.

The general result is plainly apparent, that a part, and no inconsiderable part, of the aluminum in the ingested bread made with alum baking powder was, under the action of the gastric juice, present in dissolved form in the stomach of each of the subjects of the experiments.

THE PRESENT WRITER'S OPINION OF PROFESSOR MALLET'S EXPERIMENTS AND OF THE SIGNIFICANCE OF THEIR RESULTS

In response to the request for an opinion regarding the possibly harmful effects of aluminum in the proportions (in gastric contents) that occurred in the experiments described above, I wrote in this connection to Professor Mallet as follows (Oct. 11, 1909):

The results given in your statement show clearly that well-baked bread, made with an alum baking-powder, contains aluminum in a form that will yield a surprisingly large proportion of a soluble aluminum compound or compounds to human gastric juice under normal conditions in the stomach. In one of your experiments, as much as 32.4 per cent. of the amount of aluminum introduced with the ingested bread was found in 182 c.c. of gastric contents removed "an hour after eating"—which volume was not, of course, the entire volume in the stomach at the time, to say nothing of prior natural intermittent removals of partly digested matter into the intestine. These facts suggest that in many instances more than one-third of the aluminum in the ingested portion of such bread may occur, at a time, in a *soluble* form in the digestive contents of the stomach. These data being before one—and your determination of them is conclusive assurance of their accuracy—what may be said regarding the "physiologic effects" of the aluminum that thus appears in the gastric juice in dissolved form?

I believe that aluminum, if present in the stomach, day after day, in dissolved form in such proportions would tend to modify unfavorably the gastric secretory and digestive processes. There would be repeated attacks on the mucous membrane, especially through the astringent and protein-precipitating properties of the dissolved aluminum. The associated presence of much protein material would tend to diminish such action, however, by causing the production of less toxic forms of *combined* aluminum.

I am satisfied that people with "poor digestions" would be influenced ultimately to their further disadvantage, as a rule, by meals usually containing aluminized bread. It is true that multitudes are able to withstand the deleterious influence of various poisonous substances, even for long periods, without exhibiting *distinguishable* detriment. Such seeming lack of direct harmful influence, however, is often insidiously misleadearly appearance in the urine and the rapidity and completeness of its elimination by the kidney and the reliance to be placed on its findings.

---

[4] The flour used in these experiments was examined for aluminum and yielded in the ash the equivalent of less than 1 mg. of Al_2O_3 for the largest quantity of bread eaten by any of the subjects.

3. The method of quantitative estimation of the amount of drug excreted is simple and exceedingly accurate.

4. It is of immense value from a diagnostic and prognostic standpoint in nephritis, inasmuch as it reveals the degree of functional derangement in nephritis whether of the acute or chronic variety.

5. In the cardiorenal cases the test may prove of value in determining to what degree renal insufficiency is responsible for the clinical picture presented.

6. The test has proved of value not only in diagnosing uremia from conditions simulating it, but has also successfully indicated that uremia was impending when no clinical evidence of its existence at the time was present.

7. The test has proved of great value in revealing the true renal condition in cases of urinary obstruction. It is here of more value than the urinary output of total solids, urea or total nitrogen and enables the surgeon to select a time for operation when the kidneys are in their most favorable functional condition. The improvement in the renal condition in cases of urinary obstruction, following the institution of preliminary drainage, is strikingly indicated by this test.

8. In unilateral and bilateral kidney disease the absolute amount of work done by each kidney, as well as the relative proportion, can be determined when the urines are obtained separately. We do not feel that this is always mathematically accurate, but in our series it has indicated the functional capacity to a degree not attained by any other test.

It is with the greatest pleasure that we thank Dr. Young for his early and continued interest in this work, and for the generous supply of clinical material referred to us by him, by Dr. Barker, Dr. Thayer and the other members of the hospital medical staff for the opportunity of studying the cardiac and nephritic cases, and Dr. F. W. Hobleman for his valuable assistance in carrying on the work, and Dr. Dunning of Hynson, Westcott, for kindly furnishing us with the phenol sulphonephthalein used throughout this study.

SOME OBJECTIONS TO THE USE OF ALUM BAKING-POWDER*

WILLIAM J. GIES, Ph.D.
NEW YORK

I. INTRODUCTION

During a period of about seven years I have occasionally conducted experiments on the effects of aluminum salts. These studies have convinced me that the use in food of alum or any other aluminum compound is a dangerous practice. That the aluminum ion is very toxic is well known. That "aluminized" food yields soluble aluminum compounds to gastric juice (and stomach contents) has been demonstrated. That such soluble aluminum is in part absorbed and carried to all parts of the body by the blood can no longer be doubted. That the organism can "tolerate" such treatment without suffering harmful consequences has not been shown. It is believed that the facts in this paper will give emphasis to my conviction that aluminum should be excluded from food.[1]

II. EXPERIMENTS BY HOUSE AND GIES ON THE EFFECTS OF ALUMINUM COMPOUNDS ON THE GROWTH OF SEEDLINGS

Several years ago, in collaboration with House, I published the general results of a study of the influence of aluminum compounds on typical seedlings. The essential facts in that connection were summarized in the appended statement and accompanying table (Table 1).[2]

> Although aluminum compounds appear to exist in small proportions in many plants, and occur in traces in some animals, relatively little has been learned regarding the biological effects and significance of aluminum. The authors have begun a series of studies in this connection; the first of which has been an investigation of the influence of aluminum on lupin seedlings. The methods described by True and Gies[3] were used, and the following compounds were taken: aluminum sulphate, aluminum nitrate, aluminum chlorid, aluminum-sodium chlorid, potassium alum, and ammonium alum. The accompanying table (1) presents some of the more significant results, which *represent the average of very many observations for periods of forty-eight to seventy-two hours.*
>
> In nearly all cases, in these experiments, little or no effect was produced at a concentration of $m/65,536$ [i. e., per liter the molecular weight in grams divided by 65,536]. In concentrations greater than $m/65,536$, growth usually was markedly inhibited. In concentrations less than $m/65,536$ and down to $m/1,048,576$, or $m/2,097,152$, growth was stimulated as a rule.

TABLE 1.—DATA SHOWING THE COMPARATIVE EFFECTS OF ALUMINUM COMPOUNDS ON THE GROWTH OF LUPIN SEEDLINGS

Aluminum Compound	Greatest Molecular Concentration that Permitted Slight Initial Growth	Least Molecular Concentration in Which There Was No Growth After 24 Hours	Greatest Molecular Concentration in Which Growth Was Equal to that in the Pure Water Control	Molecular Concentration in Which Initial Stimulation Took Place	Molecular Concentration in Which the Maximum Stimulation Occurred
	m/x	m/x	m/x	m/x	m/x
$Al_2(SO_4)_3$ ...	8,192	16,384	65,536	131,072	1,048,576[1]
$Al(NO_3)_3$	1,024	16,384	65,536	131,072	1,048,576
$AlCl_3$........	2,048[2]	2,048[2]	65,536[3]	131,072[4]	131,072
$AlCl_3NaCl$ ...	16,384	32,768	65,536	131,072	131,072
$KAl(SO_4)_2$ ..	1,024	4,096	32,768	65,536	{ 131,072 { 524,288
$NH_4Al(SO_4)_2$..	8,192	16,384	131,072	262;144	524,288

1. The concentration of aluminum in a $m/1,048,576$ $AlCl_3$ solution is 0.000,003 per cent.
2. The concentration of aluminum in a $m/2,048$ $AlCl_3$ solution is 0.001,3 per cent.
3. The concentration of aluminum in a $m/65,536$ $AlCl_3$ solution is 0.000,04 per cent.
4. About midway between $m/131,072$ and $m/65,536$. The concentration of aluminum in a $m/131,072$ $AlCl_3$ solution is 0.000,02 per cent.

These results showed clearly that compounds of aluminum, such as the chlorid, even when present in very minute proportions, are strong protoplasmic poisons and very toxic to growing plants.

III. MALLET'S EXPERIMENTS ON THE SOLUBILITY, IN GASTRIC CONTENTS, OF ALUMINUM COMPOUNDS CONTAINED IN BREAD MADE WITH ALUM BAKING-POWDER

Two years ago I was asked by Prof. J. W. Mallet to examine and discuss some results of Professor Mallet's investigation on the "solubility, in the stomach, of aluminum compounds contained in bread made with alum baking-powder." These results were summarized in the

[1] This paper is purposely restricted to a discussion of the work of the author and his collaborators.

[2] House and Gies: Am. Jour. Physiol., 1906, xv; Proc. Am. Physiolog. S-

[3] True rey Botanical Club, 1903, xxx, 390. Biochemical Researches 1903, i (rep

540 gm. of his blood were withdrawn. This quantity of blood contained the aluminum in 2.6 mg. of Al_2O_3.

Experiment 5.—A dog weighing 19 kilos was given 3.6188 gm. of alum (4 × 0.9047 gm.). Seven hours later, 787 gm. of his blood were subjected to analysis. This quantity of blood contained the aluminum in 10.9 mg. of Al_2O_3.

Experiment 6.—A dog weighing 17 kilos was given 2.7141 gm. of alum (3 × 0.9047 gm.). Five and three-quarters hours later, 736 gm. of his blood were analyzed. This quantity of blood contained the aluminum in 6.7 mg. of Al_2O_3.

Experiment 7.—A dog weighing 17.6 kilos was given 3.6188 gm. of alum (4 × 0.9047 gm.). Six and one-half hours later, 996 gm. of his blood were secured. This quantity of blood concontained the aluminum in 3 mg. of Al_2O_3.

Experiment 8.—A dog weighing 13.4 kilos was given 0.9047 gm. of alum *daily for eight days.* On the eighth day, six hours after the last dosage, the animal was bled to death. One thousand and fifty-eight (1,058) gm. of his blood were available. This quantity of blood contained the aluminum in 3 mg. of Al_2O_3.

Experiment 9.—A dog weighing 10 kilos was given 0.9047 gm. of alum *daily for eight days.* On the eighth day, five hours after the last dosage, the animal was bled to death and 996 gm. of his blood were secured. This quantity of blood contained the aluminum in 4.3 mg. of Al_2O_3.

In Experiments 10 and 11 aluminum was administered in biscuits baked with alum baking-powder. In these experiments (10 and 11) the dogs ingested portions of the same supplies of meat, lard and bone-ash that were available for the previous experiments; but, instead of cracker meal, they were given alum baking-powder biscuits, which were made of the ingredients that are specified in the summary in the first part of this section of the paper. The biscuits were very thoroughly baked.

Experiment 10.—A dog weighing 13 kilos was given daily, *for ten days,* about 5 gm. of alum baking powder (in baked biscuits). On the tenth day he was bled to death and 650 gm. of his blood were oxidized. This quantity of blood contained the aluminum in 2.6 mg. of Al_2O_3.

Experiment 11.—A dog weighing 11.1 kilos was given daily, *for nine days,* about 4 gm. of alum baking-powder (in baked biscuits). On the ninth day he was bled to death and 572 gm. of his blood were analyzed. This quantity of blood contained the aluminum in 1.5 mg. of Al_2O_3.

† Alum baking-powder in biscuits.

The essential data of Experiments 1 to 11, inclusive, are summarized in Table 2. The results there tabulated make it evident that aluminum passes into the blood in considerable proportions from alum in the diet. They also show that aluminum does not tend to accumulate in the blood.

These analytic data apply, of course, to the blood only at the moment of its removal from the body. Under the conditions of the experiments, it is certain that aluminum passed into and from the blood in much larger *total* quantities than those indicated. In Experiments 1 to 7, inclusive, the quantities of available blood ranged from 2.9 per cent. to 4.3 per cent. of the body weight. From three to four times as much aluminum as the quantity shown in the table was therefore contained in the whole volume of blood of the corresponding animal at the moment of bleeding (Experiments 1 to 7).

The results of Experiments 10 and 11 show clearly that the aluminum in alum baking-powder is not rendered wholly insoluble in the bread-baking process. Amounts of aluminum equal to some of those recovered after the administration of plain alum in powdered form (Experiments 1 to 9, inclusive) were found in the blood of the dogs that received the alum baking-powder biscuits.[12]

EXPERIMENTS SHOWING THAT ALUMINUM PASSES FROM THE BLOOD INTO THE FECES

The results of the foregoing experiments suggest that aluminum was not only absorbed from the gastrointestinal tract and distributed in the blood throughout the body, but also was eliminated fairly rapidly from the circulation. In considering the matter of its excretion from the body, we concluded to ascertain, first, whether aluminum passes into the feces after the parenteral introduction of aluminum chlorid.

The animals selected for four experiments in this connection were normal, vigorous dogs, weighing between 8 and 10 kilos. The daily diet was similar to that for the dogs in the first nine experiments. In each case the animal was kept on our standard diet for about ten days before feces were collected for analysis. Thereafter all the feces for the six days previous to the introduction of aluminum were carefully analyzed for aluminum.[13] *None was found in any instance in the feces passed prior to the corresponding injection.*

We selected aluminum chlorid as the salt for intravenous injection in these experiments, because it is probable that aluminum chlorid is produced from aluminized food in the stomach. A dilute solution, containing the aluminum equivalent of 0.9 mg. of Al_2O_3 per c.c. of physiologic saline solution, was very slowly

---

[12] The reader is again reminded of the fact that special care was taken to subject the biscuits to very thorough baking.

[13] The feces (Experiments 12 to 15), prior to the precipitation of any aluminum contained in them, were incinerated in a platinum dish. The ash was dissolved in dilute hydrochloric acid solution. This solution was directly subjected to the analytic procedure described in Footnote 10.

> ing, as in the case of various auto-intoxications which, until lately, have unwisely been regarded indifferently as "normal" ones and, erroneously, as without permanent, harmful influences. Unless we know *positively* that a substance which is foreign to natural foods and not intended particularly for medicinal effects, can be introduced into the stomach, repeatedly in small amounts, without *possibly* causing harmful results in some cases, either immediately or in time, I believe it is in the public interest to urge "hands off" until such supportive evidence for the substance in question is convincingly produced.
>
> I believe that aluminum, if present in the stomach day after day, in the soluble proportions you have found, would disturb the integrity of the secretory gastric cells, just as traces of soluble aluminum compounds strikingly prevent growth in plants by poisoning the cells. The fact that aluminum is normally contained in plants must not be considered apart from the very significant circumstances that the amount in which it occurs in any edible vegetable material is very minute; and practically all of that exists in forms which are there insoluble. The data in the footnote attached to your statement regarding the presence of the merest trace of aluminum in the flour you employed in your experiments, emphasize this point.
>
> Your statement does not indicate the proportion, or the conditions, of the acid in the aluminized gastric contents which you examined. Your figures for the proportions of contained aluminum may be much greater in subsequent tests, if the acidity of the gastric contents you examine later happens to be higher, as might be the case.
>
> In short, I believe such bread as you mention is likely to induce harmful digestive effects, especially if used throughout comparatively long periods, and particularly in people whose digestive processes are not vigorous or normally effective. I also feel that the public should be given the benefit of any possible doubt in this matter until it is shown, without question, that aluminized bread as commonly used cannot possibly be inimical to the health, not only of those who are robust and who apparently "can stand anything," but especially of those who are most susceptible to injury and disease. I am convinced, from a careful study of the literature on the subject, that the reasonable doubts on this score that relate to alum baking-powder have not been removed.

The correspondence with Professor Mallet also developed the fact that the aluminum in filtered gastric contents, in experiments like those conducted by Professor Mallet, is readily diffusible through parchment membranes, an observation suggesting, though not proving, that soluble aluminum compounds such as aluminum chlorid are diffusible through membranes in living organisms.

At Professor Mallet's suggestion I lately directed some experiments on the passage of aluminum from the alimentary tract into the blood. A recent paper by Prof. Matthew Steel[5] gives the results of this particular study and also presents additional data which show that aluminum passes from the blood into the feces. In the appended review of our procedure and results, free use is made of Professor Steel's paper.

IV. STEEL'S EXPERIMENTS ON THE ABSORPTION AND EXCRETION OF ALUMINUM

Professor Steel's investigation consisted of fifteen experiments on dogs. Eleven of the experiments pertained to the passage of aluminum into the blood from aluminized food, and four experiments related directly to the passage of aluminum from the blood into the feces. In Experiments 1 to 9 (described below) alum was administered in powdered form in balls of hashed meat. In Experiments 10 and 11 biscuits baked with alum baking-powder were fed. In Experiments 12 to 15, inclusive, aluminum chlorid in physiologic saline solution was injected intravenously. All the experiments were performed on full-grown, normal, healthy dogs. The animals, while under observation, were confined in cages of the kind now in constant use in this laboratory.[6] The daily food of the animals with two exceptions (Experiments 10 and 11) consisted of a mixture of hashed lean beef, lard, cracker meal, bone-ash, and water. The raw beef was taken from large supplies preserved in a frozen condition.[7]

In Experiments 10 and 11 biscuits prepared with alum baking-powder were substituted for the cracker meal. The biscuits, which were made by the process that Professor Mallet employed in his experiments, were baked with special thoroughness. The ingredients were mixed in the following proportions:[8]

	gm.
Flour	550
Sodium chlorid	8
Sucrose	5
"Bob White" baking-powder	16
Water .... Enough to make a biscuit dough	

EXPERIMENTS SHOWING THAT ALUMINUM PASSES FROM THE ALIMENTARY TRACT INTO THE BLOOD

Eleven experiments were performed to determine whether aluminum passes from aluminized food into the blood. In Experiments 1 to 9, inclusive, the aluminum was added to the food as powdered alum in balls of hashed beef.

Experiment 1.—The weight of the dog was about 24.5 kilos. He was given 0.9047 gm. of alum in order to administer aluminum equivalent to that in 100 mg. of Al_2O_3.[9] Three hours after feeding, 800 gm. of the dog's blood were taken. This quantity of blood contained the aluminum in 1.3 mg. of Al_2O_3.[10] (The dog was used in Experiments 2 and 3.)[11]

Experiment 2.—Eight days later (Experiment 1), when the dog used in Experiment 1 had practically regained his normal weight, he was given 1.8094 gm. of alum (2×0.9047 gm.). Five hours after feeding, 726 gm. of his blood were removed. This quantity of blood contained the aluminum in 1.9 mg. of Al_2O_3. (The dog was used in Experiment 3.)

Experiment 3.—Although the dog used in Experiments 1 and 2 had regained his normal weight within five days, no alum was given until eleven days after the termination of Experiment 2. At this time the dog received 3.6188 gm. of alum (4 × 0.9047 gm.). Seven hours after feeding, 857 gm. of his blood were obtained. This quantity of blood contained the aluminum in 5.9 mg. of Al_2O_3.

Experiment 4.—A dog weighing 13.4 kilos was given 1.8094 gm. of alum (2 by 0.9047 gm.). Six and one-half hours later,

[6] Gies: Am. Jour. Physiol., 1905, xv, 403.

[7] Gies: Am. Jour. Physiol., 1901, v, 235; Proc. Soc. Exper. Biol. and Med., 1908, vi, 27.

[8] The flour contained the merest trace of aluminum. The "Bob White" brand of baking-powder is a "straight alum" powder. Our samples were purchased in the open market.

[9] This quantity of Al_2O_3 was selected empirically. It is less than the equivalent amount of aluminum which is often ingested by one person in the aluminized bread of an ordinary meal.

[10] Oxidation of the blood (Experiments 1-2) was effected by running the blood from a saphenous artery through a rubber tube directly into a tared Kjeldahl flask and weighing to determine the amount of available blood, then adding concentrated nitric acid solution and heating, *slowly* at first, and finally boiling, until the solution was clear. A moderate excess of nitric acid solution was then added and the liquid boiled down to a small volume. The fluid was then treated with a fairly large volume of concentrated sulphuric acid solution for the expulsion of the nitric acid and to complete the oxidation of *the residual* organic matter. When necessary, small quantities of ammonium nitrate were added from time to time to facilitate the oxidation process. The sulphuric acid mixture was boiled for at least two hours after it became colorless, in order completely to eliminate NO_2. The residue was then dissolved in water and *made up to volume*, and the iron and aluminum determined by the Mixer-Dubois modification of the Zimmerman-Rheinhardt method: Jour. Am. Chem. Soc., 1895, xvii, 405. With this method it was found that the blood of dogs is normally free from aluminum.

[11] In order to avoid any disturbing effects of general anesthesia a local anesthetic was employed in all the surgical operations. Less than 1 c.c. of a 2 per cent. solution of cocain was used at any one operation. In no case did the dog exhibit any sign of pain.

540 gm. of his blood were withdrawn. This quantity of blood contained the aluminum in 2.6 mg. of Al_2O_3.

Experiment 5.—A dog weighing 19 kilos was given 3.6188 gm. of alum (4 × 0.9047 gm.). Seven hours later, 787 gm. of his blood were subjected to analysis. This quantity of blood contained the aluminum in 10.9 mg. of Al_2O_3.

Experiment 6.—A dog weighing 17 kilos was given 2.7141 gm. of alum (3 × 0.9047 gm.). Five and three-quarters hours later, 736 gm. of his blood were analyzed. This quantity of blood contained the aluminum in 6.7 mg. of Al_2O_3.

Experiment 7.—A dog weighing 17.6 kilos was given 3.6188 gm. of alum (4 × 0.9047 gm.). Six and one-half hours later, 996 gm. of his blood were secured. This quantity of blood concontained the aluminum in 3 mg. of Al_2O_3.

Experiment 8.—A dog weighing 13.4 kilos was given 0.9047 gm. of alum *daily for eight days.* On the eighth day, six hours after the last dosage, the animal was bled to death. One thousand and fifty-eight (1,058) gm. of his blood were available. This quantity of blood contained the aluminum in 3 mg. of Al_2O_3.

Experiment 9.—A dog weighing 10 kilos was given 0.9047 gm. of alum *daily for eight days.* On the eighth day, five hours after the last dosage, the animal was bled to death and 996 gm. of his blood were secured. This quantity of blood contained the aluminum in 4.3 mg. of Al_2O_3.

In Experiments 10 and 11 aluminum was administered in biscuits baked with alum baking-powder. In these experiments (10 and 11) the dogs ingested portions of the same supplies of meat, lard and bone-ash that were available for the previous experiments; but, instead of cracker meal, they were given alum baking-powder biscuits, which were made of the ingredients that are specified in the summary in the first part of this section of the paper. The biscuits were very thoroughly baked.

Experiment 10.—A dog weighing 13 kilos was given daily, *for ten days,* about 5 gm. of alum baking powder (in baked biscuits). On the tenth day he was bled to death and 650 gm. of his blood were oxidized. This quantity of blood contained the aluminum in 2.6 mg. of Al_2O_3.

Experiment 11.—A dog weighing 11.1 kilos was given daily, *for nine days,* about 4 gm. of alum baking-powder (in baked biscuits). On the ninth day he was bled to death and 572 gm. of his blood were analyzed. This quantity of blood contained the aluminum in 1.5 mg. of Al_2O_3.

[12] The reader is again reminded of the fact that special care was taken to subject the biscuits to very thorough baking.

[13] The feces (Experiments 12 to 15), prior to the precipitation of any aluminum contained in them, were incinerated in a platinum dish. The ash was dissolved in dilute hydrochloric acid solution. This solution was directly subjected to the analytic procedure described in Footnote 10.

injected into a saphenous vein.[14] That a portion of the injected aluminum passed from the blood into the feces under these conditions can be seen from the results of our four experiments, as summarized in Table 3.

V. GENERAL DISCUSSION

We found, in Dr. House's study of the effects of aluminum salts on germinating plants, that the aluminum ion is very destructive of protoplasm. Our results warrant the conclusion that aluminum is especially toxic to growing cells in general. That many plants contain traces of aluminum, and that some plants contain even larger proportions of that element, are well-known facts. That these proportions of aluminum occur in the living cells of plants, or that the aluminum exists in plants in soluble forms, remains to be shown, however. It is well known that the proportion of available aluminum in soluble form in fertile soils is very slight. Then, too, plants which happen to be exceptional in the matter of proportional content of aluminum are similar in that respect to animals which are unusual in their capacity to use advantageously such a poisonous element as copper. Thus the blood of the horseshoe crab contains a large proportion of copper in the form of a respiratory compound which is chemically and physiologically analogous to hemoglobin in the blood of the higher animals. No one would think of using this fact, however, as an argument in favor of the free introduction of copper sulphate into the human stomach, or its injection into the blood of a man, or its use in food. On the contrary, in spite of the fact that the blood of some animals contains copper, it is generally agreed that the administration of copper compounds to man and other mammals, even in minute quantities, induces poisonous effects. There is even less justification for the administration of substances containing aluminum.

We found in Professor Steel's experiments that when alum was administered in aluminum-free food to dogs, or when dogs ingested biscuits baked with alum baking-powder, aluminum in comparatively large amounts promptly passed into the blood. This result was obtained in each of eleven experiments. The daily diet in each of the first nine of these experiments was a full meal of hashed lean beef, cracker meal, lard and water, in quantities sufficient to maintain both constancy in weight and equilibrium in nitrogen metabolism. This diet contained bone-ash in a quantity sufficient to induce daily movements of comparatively dry, inoffensive fecal matter.[15] In the last two of these eleven experiments, biscuits made with alum baking-powder were substituted for the cracker-meal.

In spite of the presence, in the food, of these large proportions of protein and bone-ash, and of the tendencies of these materials to form insoluble products with alum, our data show that aluminum occurred in soluble form in the gastro-intestinal tract in each case of alum administration and was absorbed into the blood. It is especially important to note that this result was also obtained in the analogous experiments with the biscuits made with alum baking-powder. The biscuits had been more thoroughly baked than the bread which commonly appears on the market. The tendency of the baking process to transform the aluminum in the baking powder into an "insoluble modification" was carried to an extreme that is rarely equaled in every-day life. Nevertheless, absorption of aluminum occurred.[16]

Two objections might be raised against this conclusion regarding the absorption of aluminum from the gastro-intestinal tract into the blood. It might be assumed that our analytic method was inaccurate. Such an assumption is always in order in the consideration of any method, for none is perfect. Our preliminary work with the analytic method employed and the checks against error that were instituted, give us complete confidence, however, in the practical accuracy of the process. If slight and unavoidable errors occurred, we believe that, from the general nature of the method, they must have caused loss of aluminum and consequent diminution of the numerical result, rather than the reverse.

It might also be urged that our figures representing the amounts of aluminum which passed into the blood are too small to mean anything. It might be thought that the proportions are too minute for the causation of deleterious effects. It might even be suggested that such small proportions of aluminum are beneficial because of the possible "stimulating" action which traces of poisons frequently induce. But none of these assumptions could be shown to accord with the whole truth in the matter. The amount of aluminum in the blood at any *moment*, after the ingestion of aluminized food, is but a fraction of the quantity that may occur in the blood of the individual during a given hour or a given day—larger quantities circulate throughout the body meanwhile, under such conditions. Excretion seems to occur continuously in cases of this kind. If the aluminum which is thus carried into the blood were of any value to the organism it is improbable that the absorption of a minute proportion of aluminum would be promptly followed by the elimination of much of it. The prompt excretion of aluminum under such circumstances implies a decided physiologic repugnance.

We found, further, that absorbed aluminum circulated freely, but, as it did not show any pronounced tendency to accumulate in the blood, it is obvious that its full effects must have been registered outside of the circulation. The organism "tolerates" a great amount of injury, but it has not been shown that the development of tolerance for aluminum is either a common achievement or a desirable attainment.

It should not be forgotten that the influence of a given substance must be considered, in its practical aspects, from the standpoints of actual conditions attending its introduction into an organism. What are its effects on individuals, for example, who are temporarily ill or permanently diseased? Again, what effects are registered in a perfectly healthy individual, who takes a small quantity of the substance under consideration with similarly small quantities of equally toxic or even more noxious materials? What, for instance, may be said of the effect of aluminum from bread made with an alum baking-powder, when the bread is eaten with butter colored by a "coal-tar" dye, with jam sweetened by saccharin, with soup made from "stock" preserved by sodium salicylate and salicylic acid, with peas greened by copper sulphate, with vegetables kept from spoiling by sodium benzoate and benzoic acid, in one case, by borax and boric acid in another, to say nothing of other deleterious substances such as formaldehyd, sulphurous acid, sodium sulphite, "ether flavors," and the like, in various portions of an ordinary meal as it may happen to be served. Even if it may be reasonably urged that the effects of any one of these "foreign" substances "in the quantities eaten" are negligible, who can say that their collective action after such a meal is of no physiologic consequence? We frequently hear its said with assurance that "people go on eating all these things without ever knowing it, and yet where is the case of damage done by any of these products?" But may it not be asked in turn: Are not many cases of illness probably due to the effects of such substances in food quite unknown to those who ascribe the sickness in any instance to a different cause? It is easy to understand that relatively very slight absorption of aluminum, day after day, may ultimately (as in chronic auto-intoxications) develop biochemical incoordinations leading to perverted function, defective structure, decreased resistance to disease, or other undesirable modifications of one or more qualities or parts of the body. How many people have been obviously injured by saccharin, for example? Perhaps millions have eaten it without noting any hurtful result. Nevertheless, saccharin has recently been officially declared a dangerous sweetening agent because it does exert injurious influences, and its use as a sweetener will soon be prohibited by law. Yet, if this decision had depended on authentic reports of cases of sickness arising from the ordinary use of saccharin as a sweetening substance, its prohibition would probably never have been announced! So it is with aluminum. Alum baking-powder may be injuring thousands without affording any obvious sign of injury. While doubt remains, its use should be avoided.

---

[14] The wound healed promptly in each case.

[15] This diet, with its contained bone-ash, has been given daily to dogs in this laboratory for nearly ten years with perfectly satisfactory results. Published reference has frequently been made to the physiologic advantages of this diet and to the utility of the bone-ash given with it.

[16] This observation accords fully with Professor Mallet's findings on the solubility of aluminum from aluminized bread in the stomach, as described on a preceding page.

Professor Steel found that, when aluminum chlorid was administered intravenously in very small doses, from 5.55 per cent. to 11.11 per cent. of the aluminum passed from the blood into the feces during the three days immediately after the injection. Whether this fecal aluminum passed directly through the walls of the intestine or was excreted by the liver, or whether both channels (or others) were followed, has not yet been ascertained. The possibility that the fecal excretion of aluminum takes place by way of the bile is now under direct investigation in this laboratory.

That absorbed aluminum may be distributed to all of the tissues, and that such aluminum may accumulate there, to some extent, is a probability which has been considered but which has not yet been adequately investigated. We have already inaugurated a study of this particular problem and hope to continue the investigation until the essential facts regarding the distribution of aluminum and its possible accumulation in parts of the organism can be definitely and clearly established. We have not yet studied the quantitative excretion of aluminum in the urine.

We have supposed that when aluminum enters the blood it combines there, in part at least, with protein. We have lately prepared various aluminum-protein products. Their qualities promise to reveal the combination tendencies of aluminum when it is absorbed into the blood and carried to the tissues.

Discussion of the toxic symptoms induced in animals by aluminum will be reserved for a future consideration.

I believe the foregoing observations justify the general conclusion that, unless it can be shown definitely, and beyond a reasonable doubt, that aluminized foods are harmless, the use in food of such aluminum carriers as alum baking-powders should be prohibited by law in the interest of conservation of the best of our natural resources—the public health.

A NEW OPERATION FOR URETERAL ANASTOMOSIS

A PRELIMINARY NOTE: ANASTOMOSING THE PROXIMAL END OF A DIVIDED URETER INTO THE SIDE OF THE URETER OF THE OPPOSITE SIDE *

JOHN J. GILBRIDE, A.M., M.D.
PHILADELPHIA

I am carrying out some experimental work on an operation for anastomosing the proximal end of a divided ureter of one side with the side of the ureter of the opposite side, with the idea of saving if possible a sound kidney in individuals in whom the lower end of the ureter is badly injured or diseased as in the following conditions; namely, when the lower end of the ureter is destroyed in operations for stricture of the ureter, or in the removal or dislodgement of an impacted ureteral calculus (especially when there is a large amount of inflammatory exudate so that the ureter is apt to be too badly injured to be repaired); when the ureter is involved in disease of the pelvic structures, or otherwise injured during operations performed in the pelvis, when the continuity of the ureter cannot be restored or implanted into the bladder; and when necessary for the correction of certain urinary fistulas involving the ureter. Implanting the ureter into the intestine is unsatisfactory and the formation of a urinary fistula by stitching the ureter to the skin is undesirable unless it is absolutely necessary.

I performed this operation for the first time on a colored male cadaver in the dissecting room of the Medico-Chirurgical College, in the following manner:

The abdominal cavity was open in the median line and the ureters were exposed by making longitudinal incisions, about one inch in length, in the parietal peritoneum over each ureter as it crosses the brim of the pelvis. The right ureter was drawn up and cut at a point about two inches from the bladder. The distal end was tied with silk thread. A pair of closed hemostatic forceps was passed through the incision in the parietal peritoneum over the left ureter and gently pushed across in front of the sacrum, loosening the parietal peritoneum and pushing it forward until the point of the instrument emerged through the incision made over the right ureter. (The parietal peritoneum can be elevated even more easily by using one's fingers.) The proximal end of the right ureter was then grasped with the forceps (or one may do so with the fingers), and drawn across in front of the sacrum and behind the parietal peritoneum to be anastomosed to the side of the left uterer. The ureteral anastomosis was then completed according to the method of Van Hook, except, of course, it was an end-to-side and not an end-to-end anastomosis. The anastomosis was made by grasping the sides of the left ureter with small dissecting forceps; the walls of the ureter were thus separated and a small longitudinal opening in the ureter was made with a pair of small, sharp-pointed scissors (or one may use a scalpel) without injuring the posterior wall of the ureter. A single thread of silk armed with two straight needles was used for the anchoring suture.

The needles were introduced from within the lumen of the proximal end of the divided ureter and brought out on its anterior wall about two or three millimeters from the cut end. Then the little slit in the wall of the other ureter was held apart with small dissecting forceps,

---

* Read before the Philadelphia County Medical Society, June 14, 1911. From the Laboratory of Experimental Surgery Medico-Chirurgical College.

thus opening its lumen, and the two threaded needles were passed into its lumen and brought out on its anterior wall two or three millimeters below the end of the incision. The end of the ureter was then drawn into the other ureter and the suture tied. A suture was passed through the edges of the incision in the ureter and the wall of the other ureter at the upper end of the incision and one or two interrupted stitches were also passed through the outer coats along the sides of both ureters, forming the anastomosis. The incisions in the parietal peritoneum covering the ureters were then closed, and the operation was completed by closing the abdominal wound. If the divided ureter is too short to form the anastomosis the intact ureter may be lifted from its bed and drawn over slightly to form the union.

After performing the operation on the cadaver, I performed it on a dead dog and followed this by operating on live dogs. In the dog the serous coat of the ureter is stripped up with the ureter and carried with it; the same thing can be done on the human ureter except the peritoneum is not so adherent, and then it would be necessary to close the rent in the peritoneum caused by lifting the ureter. In this case, it would be possible to carry the ureter across in front of the peritoneum covering the sacrum, and the peritoneum could then be closed about the anastomosis.

There is one thing that those who have worked on the ureter have found—at least, it is my experience—that the ureters tolerate very little traumatism as necrosis and perforations take place under seemingly slight injury to the serous coat.

As the practical application of this procedure depends not only on its immediate results but also on its ultimate effect—that is, on the kidneys, ureters, etc.—I shall give the result in a future communication.

This operation must be thoroughly tried on animals before considering its employment on human beings, as all experimental operations on the ureters have been disappointing. At the present time it seems to me that nephrectomy under such conditions as I have mentioned above is still probably the best procedure.

A CASE OF POTASSIUM CHLORATE POISONING

M. M. SCHEID, M.D.
ROSENDALE, WIS.

Damage by borrowed medicine is frequently met. The following is an instance:

May 21, 1911, I was called to see a twenty-day-old baby with the following history: The mother knew of a neighbor's having some medicine that I had prescribed about a year previous for sore mouth, borrowed it and used it in large amounts locally on the membrane of the baby's mouth, and internally. She said that the child became irritable and began to vomit. Gradually the skin became blue in color and the stain of urine and fecal matter on the napkins became black. When I first saw the child it was cyanotic, very irritable and apparently had abdominal pain. The skin over the entire body was a deep yellow black. The conjunctivæ were yellow and the eyes had lost their luster. There was vomiting and the napkins were stained almost black. No urine for laboratory examination could be obtained. The pulse was 190. The child's condition on the second day was much worse. The pulse was 208 and temperature 99.5. The respiration was short and jerky. To Dr. Whyte, of Watertown, Wis., who was in town and who kindly consented to see the case, and to me, it seemed as if the child would surely die. The mother was very faithful in carrying out directions for elimination and on the third day the pulse fell to 180 and the deep color of the skin showed signs of fading. May 26, the color had markedly diminished and the urine began to clear. The child, however, vomited occasionally and developed a diarrhea which improved after the administration of a dose of castor oil and the withholding of all food for twelve hours. The pulse was then 140, temperature, 99. June 22, the child was back again in normal condition.

From the clinical findings, from the condition of the urine and feces, and from the history of giving potassium chlorate, the case appears to have been one of poisoning. The treatment was purely eliminative. The child was sponged frequently, given plain boiled water by mouth and rectum, put in bed near an open window and kept absolutely quiet. The second day a dose of atropin sulphate, 1/3000 grain, was given every two hours, because of its recent recommendation in collapsed condition of infants. Whether or not it did any good, I cannot say. The drug would seem contra-indicated because of the increasing pulse-rate and checking secretion. Had I had an infant stomach-tube, I should have washed out the stomach. It is possible that the reason the condition became worse on the second day was that the stomach had not been completely emptied and the cathartics failed to do what lavage could do. The child made a perfect recovery, however. This report, which, I think, illustrates the reckless use of drugs among the laity, may be of service to some one.

RUPTURE OF LEFT RECTUS MUSCLE

M. A. STERN, M.D.
SOUTH ST. PAUL, MINN.

History.—About 1 p. m., July 16, J. C., an intelligent Austrian, aged 40, was pushing a heavily loaded truck from the platform of an elevator. The elevator platform was several inches above the floor so that when he pushed the truck on to the floor, it rebounded and struck him in the abdomen. Pain and distress were marked at the time, but passed off and the patient worked the rest of the afternoon. On the morning of July 17, he reported at the office complaining of an intense pain over the site of the injury. He walked in a stooped position which seemed to ease the abdominal distress.

Examination.—The patient was well muscled and nourished. Examination indicated a moderate degree of arteriosclerosis; the pulse was 110, but of good volume and tension; temperature was 99.1. The abdomen was exquisitely tender over a spot about 2 inches square, ½ inch below and 1 inch to the left of the umbilicus; there was rigidity and a noticeable swelling at this point, and tenderness on both deep and superficial pressure.

The patient was sent to the hospital and an ice-bag applied, but by July 18 pain had increased, rigidity and tenderness had become more localized and swelling had increased. Notwithstanding a good bowel movement, an exploratory laparotomy was decided on. There was no scratch, abrasion or ecchymosis of the skin of the abdomen at any time.

Operation.—July 18, an incision was made over the swelling; as soon as the rectus muscle was reached, a considerable quantity of dark blood and recent clots welled up into the incision. The hematoma was wiped out, and the left rectus was found to be torn completely across and badly lacerated. The sheath of the muscle was intact, the peritoneum was opened, but no injury to any hollow viscus found. The muscle was sewed to the sheath and the bleeding points ligated. The abdomen was closed with drainage. There was a good recovery.

As before stated the man was pushing a heavy load and both recti were contracted to their full extent, this probably accounts for the rupture of this muscle without other internal injuries.

Therapeutics

EPIDEMIC CEREBROSPINAL MENINGITIS: SPOTTED FEVER

The present generation of medical practitioners has witnessed no greater revolution in the therapeutic measures employed in a disease, nor in the results following the use of such new treatment, than has taken place during the last five years in the case of epidemic cerebrospinal meningitis. This disease, also known as spotted fever, and more concisely designated as epidemic meningitis, is an infectious disease characterized by a purulent inflammation of the inner covering of the brain and spinal cord. It has been known to medical observers for about a century, and has been recognized as a terrible affliction, and dreaded by the profession and the laity alike.

Weichselbaum, in 1887, described an organism which he found in this disease, to which the name *Diplococcus intercellularis meningitidis* was given, and which has also been known by the shorter designation of meningococcus. Jäger, in 1895, demonstrated that this organism is the cause of epidemic cerebrospinal meningitis. It is found in the cerebrospinal fluid in well-developed cases of the disease. It is an organism of rather delicate vitality, and its activity seems to be impaired by fresh air and sunshine. It is sometimes found in the crypts of the tonsils and pharynx of persons who do not have an acute attack of the disease. It is probably transmitted through the secretions from the nose and mouth, and is received in this way by persons who subsequently become ill with the disease.

It has been found rather difficult to demonstrate the directly contagious nature of the disease. It was for many years the custom to admit patients with the disease to the wards of general hospitals, and for a long time it was believed that new cases did not arise from cases so present in the wards. Later, more careful observation has seemed to show that occasional cases do arise in wards from direct transmission, so that at the present time it is customary not to admit patients with this disease to the general wards of the hospitals, but to send them to hospitals designed especially for contagious and infectious diseases.

Approximately 15 per cent. of the patients with this disease are children under 2 years of age (and about 60 per cent. are children between the ages of 2 and 15.

Predisposing causes to this disease seem to be unhygienic surroundings and "crowd poisoning." In other words, it seems most likely to occur in epidemic form in cold weather and among children who are living in crowded apartments where there is but little sunlight, and where the windows are kept closed to keep the apartments warm. While it sometimes seems that a debilitated state of the system predisposes to this disease, it is also true that during epidemics some robust and apparently very well children acquire the disease.

An epidemic does not seem to spread out or develop from a single focus, but, like influenza, may attack people in different parts of a region at the same time.

Not infrequently the infection has been found to start from the pharyngeal tonsil, and thus enter the cranium through the sphenoid bone, and then along the vessels through the sphenoidal foramina into the base of the brain and sella turcica. Some investigations have seemed to show that the infection traveled along the lymph-channels rather than the blood-channels, and these investigations did not show that the infection went through the cribriform plate of the ethmoid.

In an acute attack of the disease the organs most affected are the meninges of the brain and spinal cord. The pia-arachnoid membrane is most affected, and it may show all grades of inflammation, but there is almost always more or less purulent exudate. The pus varies greatly in amount, and some parts of this membrane may be more affected than other parts. The region where there is the greatest amount of inflammation and pressure is indicated by peripheral nerve signs. As soon as there is exudate enough to cause pressure, the pressure alone accounts for many of the symptoms. The exudate does not, as a rule, penetrate into the brain or spinal cord tissue, but by pressure on the nerves at the base of the brain or spinal cord causes local paralysis.

At post-mortem examinations in this disease, the pia mater will be found covered with thin, yellowish pus, and there may be small petechial hemorrhages on the surface of the brain. The ventricles are also generally found filled with an exudate. The rapidity with which this condition can take place and cause death in some fulminating cases makes it one of the most serious diseases that we have to treat.

Although manifestations of this disease in its acute variety is limited to the cerebrospinal system, if the disease is protracted, there is hardly a part of the body that may not become affected. The lymph-glands and spleen generally do not enlarge, and metastatic abscesses do not occur, but pleurisy, pneumonia, endocarditis, pericarditis, nephritis, arthritis, neuritis, blindness and deafness can occur, to say nothing of later signs of cerebral degeneration.

The symptoms, as in all infectious disease, vary greatly in different cases. Sometimes the disease is so mild as not to confine the patient to bed. In other instances the patient is sick, but not seriously so, and soon recovers. These cases are distinguished as abortive cases, and no doubt they are frequently the direct cause of the inexplicable spread of the disease. The majority of cases, however, are very serious. The temperature is irregular; it may be high, if there is a condition of irritation or excitement of the nervous system, or may be low, if there is a condition of shock. The pulse is often very irregular; rapid if the patient is alert, and slow and gradually weakening, if the patient is in more or less stupor. Often the first symptoms are a slight congestion of the nose and throat and perhaps of the conjunctivæ, and often slight deafness. There may be some pains referred to the joints and lower extremities. There may be intense backache, shoulder pains and pains down the arms. There is always severe headache, with soon more or less stiffening of the muscles of the back of the neck. There is irritability, restlessness, often photophobia, and before the deafness perhaps a hypersensitiveness to aural impressions. In some instances the initial symptom may be a severe convulsion followed by unconsciousness. Such a case is of course a severe one. In some instances the nervous symptoms are preceded by a chill, followed by a quick rise in temperature.

The secondary symptoms depend entirely on where the greatest inflammation is located in the cerebrospinal axis and where the first pressure and the greatest pressure from exudates is exerted. Motor symptoms due to irritation of the roots of the motor nerves are early seen. These are, besides the rigidity of the muscles of the back of the neck and sometimes of the trunk, the so-called Kernig sign. This consists of an inability to extend the leg in line with the thigh, the latter having been flexed at a right angle with the body, without causing pain and contraction both of the muscles of the leg and of the back.

Besides the above symptoms, disturbances of the stomach and intestines are frequent, and reflex, or projectile vomiting, due to cerebral irritation, is a common symptom. There is generally constipation due to retarded peristalsis; often retraction or flattening of the abdominal wall. Petechial spots occur in about 25 per cent. of these patients, and are more or less distributed over the body. This gives the name to the disease of spotted fever. There is frequently observed the so-called *tache cérébrale,* which consists of a red mark which persists for several minutes after the finger-nail has been rubbed across the skin; or it may occur on the face on the side on which the child may be lying. Delirium is a frequent and early symptom, and is generally succeeded by coma, if the disease does not abate or the pressure of the exudate on the brain is not removed. The pupils are generally at first contracted due to the irritation, then often become unequal, and later, if the disease progresses to exudate and pressure, are dilated and will not then react to light.

If the pressure on the floor of the fourth ventricle and on the medulla becomes increased, the pulse becomes slow and intermittent, and Cheyne-Stokes respiration occurs.

After recovery there is often a lingering stiffness of the muscles, stiffening of the joints, maybe neuritis, and maybe some deafness, and, as above stated, there may be actual deterioration.

The discovery of the *Diplococcus intercellularis* as a cause of this disease, and this germ being almost invariably found in the spinal fluid obtained from lumbar puncture, when the disease is present, makes a presumptive diagnosis require the backing of the bacteriologic fact. In hospitals lumbar puncture is an exceedingly simple matter, but in private practice a physician may not think it immediately advisable, even if he has the technical knowledge to puncture the spinal canal properly, to apply this test, even if some symptoms look meningeal. However, if the meningeal symptoms are positive, or if doubtful symptoms do not in a few hours clear up, lumbar diagnostic puncture should be done.

While the most characteristic symptoms, when they are present, of a cerebrospinal meningitis are the early occurrence of a convulsion, with fever, and rigidity of the muscles of the back and neck, accompanied by projectile vomiting, headache, and photophobia, a correct diagnosis of the particular germ that is causing the disease can be made only from a lumbar puncture.

At the beginning of an epidemic, or when sporadic cases are encountered, the possibility of the occurrence of this disease is frequently overlooked, and a diagnosis of some other form of disease may be made and even persisted in until the death certificate has been written. On the other hand, in the presence of an epidemic of the disease, it frequently happens that other diseases are mistakenly called epidemic meningitis, until irrefutable evidence proves that it is not.

The diseases with which epidemic meningitis are most likely to be confounded are lobar pneumonia, gastro-intestinal intoxication, anterior poliomyelitis, otitis media, encephalitis, and typhoid fever. Besides these, other forms of meningitis which are not caused by the meningococcus must be taken into account in making the differential diagnosis. The most common of these diseases is tuberculous meningitis. Less common forms are the pneumococcus meningitis, streptococcus meningitis, and influenza meningitis.

Where the symptoms are less striking than in the group which is enumerated, the difficulty of diagnosis is often very great, and can be made only by a careful examination of the patient and by a gradual exclusion of other diseases. In every case, if possible, lumbar puncture should be done, and by examination of the fluid so obtained a definite diagnosis can generally be promptly made. The fluid is, as a rule, somewhat turbid, and the meningococcus can generally be found. Polymorphonuclear cells are also usually present.

Since the discovery, in the Rockefeller Laboratory, by Flexner and Jobling, in 1908, of the antimeningitic serum, there seems to be but one way of treating the disease, viz., by the injection of this serum. The working rule is as follows: When the presence of this disease is suspected, a lumbar puncture should at once be made. If the fluid obtained is turbid, the serum should at once be administered. This is usually done with a syringe and through the same needle through which the cerebrospinal fluid has been obtained. It is customary to inject an amount not larger than has been withdrawn. This is usually about 30 c.c. While some prefer to inject with a syringe, others prefer to administer it through a glass funnel connected with the needle, believing that in this way they are less likely to produce injurious pressure on the central nervous system, which has sometimes been observed. These injections are generally repeated daily until four injections have been made, unless the patient is obviously convalescent before the later injections are due. If the patient grows worse after the first injection, a second may be given after twelve hours instead of waiting twenty-four. If the first injection does not show positive benefit, a larger amount, 45 c.c., may be given at the second injection. After the four injections it is customary to wait for two or three days, and, if the symptoms are still serious, to give another series of injections.

Previous to the introduction of this serum the mortality from the disease seems to have been practically about 75 per cent., although various observers, basing their conclusions on a limited number of cases, have represented the mortality to be less than this. Under the use of the serum, the mortality, taking a large number of cases together, has been reduced to about 25 per cent. Comparing small groups of cases, it is found that the earlier the injections are commenced, the less the mortality. The results obtained in children under 2 years of age are not so good as those obtained in older children, from 2 to 15 years of age. However, this representation of the improved statistics of mortality does not give a complete picture of the advantages to be obtained from the serum treatment. While these statistics indicate a very greatly increased benefit as regards the prevention of death, they do not show, what observers constantly report, the very great improvement in the results obtained by treatment, in that fewer patients become chronic invalids from hydrocephalus, from deterioration of mental power, and from deterioration of the general health. Under the old forms of treatment the condition of many who did not die was so bad that it was frequently said that the patient who died was more fortunate than the one who lived. The blindness, the deafness, the localized paralysis, the impaired mentality which were commonly seen in patients who recovered under old forms of treatment, are rarely seen after recovery from the serum treatment. The duration of the disease also is greatly lessened by this treatment.

Under old forms of treatment cases frequently persisted for weeks or months. Now such cases are rare.

Besides the specific treatment, the child's throat should be sprayed, or he should gargle with an antiseptic such as hydrogen peroxid solution in dilution of 1 part to 5 of warm water. The nostrils should be sprayed and cleansed with a warm, weak alkaline solution such as a diluted liquor antisepticus alkalinus. The eyes, if there is conjunctivitis, should be bathed with boric acid solutions. Painful joints should be wrapped up in cotton, and the child's body and limbs should be placed in the position that causes the least pain and is found the most comfortable.

A calomel purge should be given, followed perhaps by a gentle saline. If there is vomiting or entire loss of appetite, food should not be urged for the first two or three days, as the child is better without it. Plenty of water should be given him. If vomiting persists and nausea is severe, and especially if there is severe pain, morphin should be given to the point of relieving these symptoms. The amount and frequency depends on the age of the child and the intensity of the pain. It should be remembered that there is no more excuse for allowing a child to suffer pain than there would be for trying to compel an adult to suffer pain. The morphin should be administered hypodermatically. If the pain is not severe, bromids or chloral will cause much-needed sleep, muscle relaxation, and nerve rest, all of which three factors are exceedingly necessary in any meningitis.

After the first day or two, the simplest nutriment, in small amounts should be given, at three-hour intervals. The best nutriment for this disease is milk, oatmeal gruel, egg albumin, and later on, meat juice.

The medicinal treatment that will aid in relieving the inflammation caused by the disease while the antitoxin is combating the specific germ, is ergot, administered hypodermatically. This drug quiets cerebral excitement and delirium, contracts the blood-vessels, especially of the central nervous system, and can be contra-indicated only when the heart is excessively active and the blood-pressure high. If such contra-indication was present, the symptoms would be relieved by nitroglycerin, or better, by blood-letting. Such a contra-indication, however, is rarely present, and the ergot should be given intramuscularly into the deltoid, or into the calves of the legs if many injections must be made. The amount advisable is a hypodermic syringeful of a good aseptic ergot; this dose for an adult. A child of ten should receive half this dose, 1 c.c. (15 minims), and a child five years old one-fourth of this dose (7½ minims); or each a proportionate part of a more concentrated solution of ergot as occurs in an aseptic ampule. This dose should be repeated in three hours, if there seems to be no action from it, and then after that once in six hours until there is a marked improvement of the symptoms. The ergot not only acts satisfactorily on the nervous system in relieving congestion and quieting the patient, but also increases and prolongs the action of any dose of morphin which it is necessary to give. In other words, less morphin need be given for severe pain in meningitis if ergot is given coincidently. If the injection of ergot causes temporary local pain and swelling, an ordinary wet dressing of 1 part of alcohol to 3 or 4 parts of warm water bandaged over the part will soon cause relief. If the skin is properly cleaned and the needle and syringe aseptic, and the preparation of ergot a good one, there will never be an abscess.

Alcohol is never indicated; neither should any drug that would excite the brain or spinal cord be given, such as quinin, strychnin, caffein, etc.

A very useful local treatment is ice. The ice-cap to the head and the spinal ice-bag, if the child will allow it, is certainly good treatment. If the child will not allow these cold applications, or if the child is young and is easily depressed by an ice-cap on the head, or if the temperature is low, and especially if the patient is stupid, hot sponge baths are better than ice applications. The more the blood is brought to the surface of the body, the less will be the internal congestion.

Besides the lumbar puncture for diagnostic purposes and for the injection of the antitoxin, the relief of cerebral pressure from lumbar puncture should not be forgotten, and many a life has been saved, before the antitoxin was discovered, by one or more removals of this extra fluid allowing relief from dangerous pressure and coma. In other words, prolonged coma from pressure should not be allowed, if its removal by way of the spinal canal is possible. It is quite probable, however, at times when lumbar puncture is not satisfactory, if properly done, that a purulent plug has stopped the free exit of fluid from the brain to the spinal canal.

The general care of the patient is the same as for any serious illness. The sick-room should be a large, thoroughly ventilated room, quiet if possible, and not too dark. It is better properly to shade or even screen the patient's eyes and allow the sun to enter the room. No talking, no unnecessary noise, and no officiousness of nurses or parents should be allowed to occur. The feet should never be allowed to become cold. The bowels should be moved daily, after the first purging, in the easiest possible manner, perhaps with a glycerin suppository. An albuminuria may occur, but it requires no special treatment, except possibly the administration of more water to cause the urine to be less concentrated. Also, if albuminuria occurs, ice applications to the back should probably be stopped.

As soon as the patient begins to recover, the ergot is of course stopped, and an iodid seems advisable. It seems to be a clinical fact that small doses of iodid aid in the resorption of exudates. At any rate, they apparently work only for good. Sodium iodid is the salt that should be selected, and the dose should be small, not more than 0.10 gm. (2 grains) three times a day, for a child 5 years old. Large excessive doses of iodid are absolutely not indicated in any meningitis, unless it is syphilitic.

Convalescence calls for iron in small doses, and possibly for some bitter tonic. The patient should remain in bed at least a week after the cessation of all active symptoms. Later convalescence should be very slow, and the resumption of any work or duty postponed as long as possible. Any muscles or joints that are stiff should receive massage, and any paralyzed muscles should be given electricity soon, lest they atrophy. The early applications, however, should be mild, lest too much stimulation be given to the nervous centers. If there are later any adhesions in or around joints, chloroform should be administered and they should be forcibly broken up.

Derivation of the Word Epilepsy.—The word "epilepsy" is derived from the Greek. The original word in that language was *epi lambeino*, meaning "to fall on." The original spelling more nearly approached the Greek word than does the present; instead of "epilepsy" it was "epilency." Trevisa, in 1398, writing of it as was the custom in the fourteenth century, spelled it epilency.—E. L. Hunt in *Medical Record*.

EPIDEMIC DROPSY

The so-called "epidemic dropsy" of India first attracted attention in 1877, when an outbreak took place in Calcutta. The succeeding few years witnessed a somewhat limited spread of the disease, but it apparently died out completely, and for about twenty years no fresh cases were reported. In 1901, however, cases clinically similar to the earlier ones were again observed in Calcutta, and in the following decade the disease attained such importance as to cause a government investigation. A report of the results obtained so far has been made recently by Greig,[1] and his findings are of considerable interest in view of the close similarity shown by this affection to beriberi.

Although some resemblance between epidemic dropsy and beriberi had long been noted, the infrequency of peripheral neuritis in the former led some observers to consider it an entirely distinct disease, and indeed its clinical aspects would seem to warrant such a conclusion. The most constant and characteristic symptom, as the name indicates, is the marked edema, for the most part confined to the skin and subcutaneous tissues, though the serous cavities also are invaded in severe cases. The occurrence of neuritis is noted by different observers, but all agree that it is by no means so important a feature of this disease as of beriberi. Greig calls attention to the fact that the clinical picture resembles very closely that of "ship beriberi," in which dropsy is the chief symptom, and neuritis of relatively secondary importance. Besides ship beriberi, the "prison dropsy" of the early part of the nineteenth century also bears marked resemblance to the Indian affection.

The investigation attacked the problem on several distinct sides. Although the non-infectivity of epidemic dropsy has been commonly acknowledged, this was made the subject of experimental work, with entirely negative results. Monkeys inoculated with freshly obtained blood gave no evidence of infection, and all attempts at isolation or observation of a peculiar organism in blood, urine, feces and dropsical effusion were unsuccessful. The distribution, too, of the epidemic gave evidence of its non-infectiousness. Practically all cases occurred among Bengalis, while the Marwaris (Hindus) living in the heart of the affected portions of the city remained almost wholly free from the disease. So, too, none of the better class of Europeans contracted it; and although in the hospitals no attempt at segregation was made, no dissemination to other patients occurred. A map giving the distribution of the fatal cases illustrates these features strikingly. Five of the more populous wards were either wholly free from fatal cases or almost so. Of these, two are inhabited mainly by Marwaris, and the remainder form the European quarter of Calcutta, while the heavily affected wards are those occupied by the Bengalis. Such a distinction might, of course, argue for racial susceptibility, were it not for the fact that Eurasians and poor Europeans at times contract the disease, and that a much more obvious and probable explanation is forthcoming.

In the dietary of the Bengalis rice is the predominant feature, supplemented to some extent by "ata"—finely sifted wheat flour. The Marwaris, on the other hand, live mainly on the pulse-grains, and the varied diet of the well-to-do European needs no comment. Since the advent of steam mills into India, the rice is for the most part polished, with the result that the phosphated elements of the grain are largely removed, as is also the case with the wheat flour used by the Bengalis. The pulses are comparatively rich in phosphatic elements, and a comparison between the typical dietary of a Marwari and a Bengali shows from three to four times the amount of phosphoric anhydrid in the former as in the latter.

Additional evidence in favor of dietary one-sidedness as a cause of the disease is afforded by the fact that those among the Bengalis who most frequently eat meat—the men, and children of both sexes—showed the fewest fatalities, while among the adult females, who eat meat seldom, they were much more numerous, and among the widows, who by religion are allowed no meat, deaths were most frequent. Animal experiments, too, showed the harmful effects of the Bengali dietary. The symptoms so produced, however, resemble those of beriberi more closely than epidemic dropsy, and are similar to those observed by previous investigators.

As to the epidemic character of the affection, Greig notes that the outbreaks occur at the time of high food prices, and cease coincidently with the fall in food values. The Bengali, he considers, lives normally in a state of "nutritional instability," and it needs only the extra strain of famine to overwhelm the balance and bring on acute disease.

Why, with causes apparently so similar, the disease should differ to such an extent from beriberi in symptomatology, is difficult to say. The fact may be of significance that Megaw,[2] in reporting cases of epidemic dropsy observed in Eurasians and poor Europeans, gives neuritis as a marked and constant symptom. So it is possible that race, or such minor dietetic difference as may result from it, may be a factor in this phase of the subject.

PELLAGRA

Medical and press reports indicate the increasing prevalence of pellagra in different sections of the country. From Kentucky, Tennessee, North and South Carolina and Georgia come reports of increasing numbers of cases, some of them in localities where the disease had not previously been detected. These reports in all probability mark the annual recrudescence of the disease, and indicate that it is increasing from year to year, at least in some localities, and at a rate that demands serious consideration.

The evident increase in the number of cases, the high mortality attending the disease, and the lack of knowledge regarding its etiology and prevention, have created some feeling of alarm among the people of infected localities lest the disease might become widely epidemic. Judging from the experience of Italy, such an event is not impossible, since in that country the disease, soon after its appearance, became wide-spread and was attended by a high rate of mortality.

Accurate data regarding the prevalence of the disease in this country would at the present time be of the greatest value, but unfortunately these are not available since in only four states is pellagra required to be reported, and in only one of these are such reports required by law. Were these data available for the period since pellagra was first reported in the United States, it is probable that some idea would be gained as to the extension of the disease, and some light might also be thrown on the etiology and other phases of the problem.

No appreciable advances have been made in our knowledge of etiology and prevention in the recent past. The maize theory of the origin of the disease appears to be attracting less attention on the part of students of the disease. Sambon's hypothesis regarding the agency of flies of the genus *Simulium* appears as yet to have few supporters in this country, although Roberts[1] of Atlanta in a recent paper states that, from observations made in his section, conditions are very similar there to those described by Sambon in Italy where the disease prevails.

Alessandrini of Rome, on the other hand, attributes pellagra to a water-borne trematode of the genus *Filaria*.

Neither of these interesting views as to the parasitic origin of the disease has been confirmed. In fact, definite knowledge regarding the etiology of pellagra is utterly lacking, and the problem is one, therefore, that calls for urgent study and early solution.

Any true estimate of the significance of pellagra in the United States and its importance in future must be based largely on knowledge of its cause. The adoption of adequate preventive measures also depends on this factor.

The practically universal view of the non-contagiousness of pellagra renders quarantine inadvisable and unnecessary, and so far as known this measure has not been adopted by experienced authorities in their struggles against the disease. That health authorities and physicians generally are alive to the necessity of vigorous action, however, is shown by the interest taken by them in the subject. On the other hand, press reports and editorial comments indicate that the public is becoming much exercised over the situation. In an editorial in one of the southern papers,[2] the situation in North Carolina is referred to as alarming, and the medical profession is called on to devote more of its time and thought to the problems involved.

On the whole, the pellagra situation must be viewed with serious concern. The disease has been reported from more than thirty states, its area is extending, and its presence is a menace to the physical and mental integrity of large numbers of people. *It therefore* becomes one of the most, if not the most, important public health problem of the present, and as such, adequate provision should be made for its thorough investigation by federal and state health authorities.

THE FRENCH MARRIAGE LAWS

As mentioned[1] by our Paris correspondent, Dr. Bertillon, *chef de travaux* of the municipal statistics of Paris, believes that the success of the present French marriage laws in promoting marriage shows how much laws can do to improve social customs and conditions, and thereby justifies legislation to promote increase in the birth-rate. An "administrative nihilist" of Herbert Spencer's school would perhaps have said that the results of the change in the law showed how much law could do to hamper social progress, since the improvement noted since 1907 seems to be due to the removal of burdensome formalities and restrictions with which the old law surrounded marriage. We are inclined, on the whole, to agree with Dr. Bertillon; but in the operation of the old law and the new we see, in addition, how much legislators can accomplish which they did not desire or foresee.

The French ideal of the family has, to most English-speaking people, an archeologic interest. We ourselves look on the family in the stricter sense as normally subject to growth and decay during a single generation. It comes into existence with a marriage; it has its fullest bloom while the children of that marriage are under their parents' care; it begins to undergo autumnal decadence as those children leave the home circle to found families of their own or to live their independent lives; and it comes to an end with the death of the parents or last remaining members of the home circle. In the ancient world, on the other hand, the family was immortal, or as nearly so as pious care could make it. The *patria potestas* never lapsed; the personality of the head of the family might change, but there always was an absolute head. Individual members of the household might die, but the family existed from generation to generation, held together under one central authority, united by common interests and common experiences.

---

[1] THE JOURNAL, June 10, 1911, p. 1734.

Something of this antique permanence and solidarity it was the object of the French law to preserve in the French family. That law and custom both were instrumental in rendering family ties especially strong and permanent in France is the testimony of the French themselves and of foreign observers best qualified to judge. The marriage law contributed to this end by requiring candidates for marriage, whatever their age, to produce either the consent of their parents or proof of their death. It is true that the law did permit a son or daughter of marriageable age to dispense with the parents' consent after going through a process known as *sommation respectueuse;* but this was considered "respectful" only in name. Sooner than subject a parent to such an indignity, any right-feeling French son or daughter would submit to lifelong celibacy; in fact, the scandal of an irregular union seems to have been less dreaded in some instances than that of a *sommation respectueuse* to the parents of one or the other of the pair. Thus, while on the one hand the old law was indeed most powerful in preserving the old family ideals (within, apparently, a sphere constantly narrowed by the celibacy of those whom it prevented from marrying), on the other hand it lent a kind of desperate sanction to those irregular households which could not be called families. And thus perhaps is partially explained the apparent contradiction between the views of those who consider the French the embodiment of all the domestic virtues and those who find in them the antithesis of all domesticity.

The ancient ideal of the French family, beautiful as it is in many aspects, seems an anachronism, and attempts to preserve it longer by artificial means would have been as disastrous as the attempt to preserve the Macedonian phalanx in modern warfare. The simplification of the French marriage law has apparently come none too soon. The old form of the family, admirable as it was in its own day, could be preserved in this age only at the cost of growing demoralization.

Current Comment

"H. L. HARRIS" AND DR. WILEY

Our old friend, "H. L. Harris," is again "on the job." The newspaper editors over the country are receiving a stock letter signed "H. L. Harris," the tenor of which is to the effect that Dr. Wiley is not the efficient public servant most people think he is. After explaining what a negligible quantity Dr. Wiley is in the enforcement of the Food and Drugs Act, H. L. Harris delivers himself of this gem:

> "There is really no danger to health and life from partaking of adulterated condiments, etc., and the bulk of food which mankind consumes, such as bread, meat, potatoes, fresh vegetables, fresh fruits, nuts, etc., never has been adulterated. . ."

Many newspapers know the true inwardness of Mr. Harris' communications. Some newspapers do not. As we have explained to our readers on several[1] occasions, "H. L. Harris" is one of the names under which the press agent for the borax trust—The Pacific Coast Borax Co., 100 Williams Street, New York City—writes. He sometimes uses the name "H. H. Langdon" and on the stationery which carries this name, calls himself a "Food Expert," and writes from a different address—427 West 22nd St. A few years back many medical journals printed H. L. Harris' articles on "Food Preservatives" under the belief that the author was a chemist instead of a publicity agent for the manufacturers of chemical food preservatives. After the reading pages of the medical journals were closed to this form of advertising, "H. L. Harris" sent letters to the newspapers on the subject of ptomain poisoning. Every case of alleged ptomain poisoning reported in the newspapers was collected by the borax concern and a stock letter signed "H. L. Harris" was immediately dispatched to the newspaper containing the report. These letters addressed "to the editor" first referred to the case of poisoning that had been recorded and then went on to tell how many thousands of cases of ptomain poisoning there had been since the pure food law had prohibited the use of borax in foods! Of course, it may be remarked, there is no particular reason why manufacturers of chemical preservatives should not send out articles to the daily press extolling their wares and criticizing the government officials who are trying to protect the public against those who would sell "medicated garbage" as foodstuffs. There is an excellent reason, however, why such articles should bear the name of the concern in whose interest they are written and not the variable cognomen of a "publicist." If the Pacific Coast Borax Co. should send out, on its own stationery, a letter signed by the company, stating: "We think Dr. Wiley a very undesirable man for the position of Chief of the Bureau of Chemistry, and we are fully convinced that borax is one of the most harmless and necessary ingredients of foodstuffs"—if, we say, such a letter were sent to newspapers there would be no grounds for criticism. But unfortunately, food dopers don't do business that way.

THE SANATORIUM AND THE DISPENSARY IN TUBERCULOSIS WORK

In a communication in this issue, Lawrason Brown calls attention to the need of accurate figures to prove or disprove the value of sanatorium and dispensary treatment of tuberculosis in its ultimate results. With the tremendous number of consumptives throughout the country it is impossible that all should be treated in sanatoriums, and besides, the solution of the economic problems involved are almost impossible by any state or community. Many private sanatoriums have been established for the treatment of tuberculosis, and a number of states have also established institutions of this sort. Besides these, lodges and philanthropic societies have also established sanatoriums for the purpose. On account of the large number of patients who need this sort of treatment none can remain long in these institutions, and whether they secure permanent benefit in a sufficient number of cases to justify our faith in the method, there are no accurate figures to show. Consumption is not cured in a few months. It requires three, four or even five years to effect a cure, whereas few consumptives stay in sanatoriums longer than six months. To overcome this difficulty, dispensaries have been established really more for the guidance and advice of patients and their families than to give individual treatment with the hope of cure. These dispensaries have no doubt done much good in the way of informing the patient as to the proper mode of life and habits for him to follow both for his own good and for the protection of those with whom he comes in contact. They have been the means, also, of aiding in the early diagnosis of many cases in patients who would otherwise have gone to physicians or to sanatoriums too late for much good to be done them in the way of care or treatment. But it is important to know accurately what the results of this treatment are. It is not the statistics covering the results of a few months of treatment, but the ultimate results, which constitute the actual test of the value of the treatment. Our correspondent, therefore, makes a plea for concerted work by sanatoriums and dispensaries in treating and following up these patients for a considerable period of time to ascertain the exact value of the treatment in saving the lives of consumptives. The sanatorium and dispensary idea has been gone into quite enthusiastically, and much money and energy are being spent by public and private charity for this form of treatment, without exact knowledge of its ultimate value.

---

[1] Editorially in The Journal A. M. A., Oct. 5, 1907; Feb. 13, 1909; Jan. 1, 1910; March 12, 1910. Some of this matter has been reprinted in leaflet form and will be sent on receipt of stamp.

COMPULSORY NOTIFICATION OF POLIOMYELITIS

At present, twenty-three states require that the health authorities be notified of cases of infantile paralysis. Other states will no doubt soon be in line. While the disease in epidemic form has prevailed in some countries of Europe for a longer time than in this country, and notification has been and is required, France seems to be one of those in which this has not been a requirement of the health authorities. The Paris Academy of Medicine, a little while ago, appointed a committee to consider the question of the propriety of obligatory notification of acute anterior poliomyelitis. On the recommendation of this committee, the academy advises that notification be made compulsory and that it should apply not only to typical cases, but also to doubtful ones, and furthermore, that it should be made at all times even in the absence of an epidemic. It is also recommended that children who have been in close relation with patients suffering from the disease be forbidden attendance at school for three weeks and that disinfection of the rooms at the termination of the disease be undertaken. Although the exact cause of this disease and the precise method of its transmission have not been determined, yet its infectious nature is so well established by clinical observation and experiment that compulsory notification is justified and should be required wherever the disease exists.

Medical News

CALIFORNIA

Medical Shop for Hospital.—Dr. Charles E. Zerfing, police surgeon of Los Angeles, is planning the establishment of a medical shop in the basement of the Receiving Hospital, in which will be made all the apparatus and equipment necessary to be used in all cases of emergency surgery. During the last year more than 21,000 patients were treated in the Receiving Hospital.

The Campaign Against Squirrels.—Dr. Friench Simpson, U. S. P. H. and M.-H. S., the federal expert in charge of the squirrel extermination campaign for the Visalia district, reports that in more than one hundred places under reinspection in the district, fifty were found to be absolutely free from squirrels. Assurance was given that while it will require several years of persistent effort squirrels can finally be exterminated.

Personal.—Dr. George W. Lasher, Los Angeles, is reported to be critically ill with cerebral hemorrhage at the home of Dr. William F. Perry, Los Angeles.——Dr. William W. Cross, Fresno, has been placed in charge of the branch of hygienic laboratory of the State Board of Health at Fresno.——Dr. Edwin B. McKillop of the Los Angeles County Hospital was struck by a car and painfully injured August 11.——Dr. Harold A. Miller and Dr. James A. Ellis have resigned as members of the Alameda Board of Health.——Dr. Henry C. Peterson, Stockton, has returned from abroad.——Dr. J. Perry Lewis, San Diego, fractured his leg and clavicle while cranking his automobile August 8.

COLORADO

Personal.—Dr. Maynard C. Harding, Ault, has been placed in charge of the Medical Mission of the Presbyterian Board at Soon-Chun, China.——Dr. William W. Arnold has been elected president of the Indiana Society of Colorado Springs.——Dr. Willis G. Mudd has been appointed a police surgeon of Denver.

New State Board Members.—Dr. Arnold Stedman has been appointed a member of the State Board of Health to succeed Dr. Lewis E. Lemen, Denver; Dr. James R. Arneill, Denver, to succeed Dr. Josiah N. Hall, Denver, and Dr. Charles S. Morrison, Colorado City, to succeed Dr. Vivian Russell Pennock, Longmont.

State Medical Society Meeting.—The forty-first annual meeting of the Colorado State Medical Society, held in Steamboat Springs, August 15 to 17, resolutions were unanimously adopted endorsing the policy and the work of Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry of the Department of Agriculture, Washington, D. C. Pueblo was selected as the next place of meeting and the following officers were elected: President, Dr. Walter A. Jayne, Denver; vice-presidents, Drs. William F. Singer, Pueblo, Horace C. Dodge, Steamboat Springs, Frank L. Dennis, Colorado Springs, and Benjamin B. Beshoar, Trinidad; secretary, Dr. Melville Black, Denver (reelected); treasurer, Dr. George W. Miehl, Denver; publicity committee, the secretary and Dr. Edward Jackson, Denver; councilors, Drs. Jacob C. Chipman, Sterling, and Arthur G. Taylor, Grand Junction, and delegate to the American Medical Association, Dr. Hubert Work, Pueblo.

ILLINOIS

Inspection of Dairies.—An inspection of all dairies in the state, containing four or more than four cows, is being made by Dr. Charles E. Crawford, Rockford, chief inspector of the State Board of Health and his assistants, and on its completion the board will have an original report on every dairy in the state and full information as to its sanitary condition.

Personal.—Dr. Joseph P. Pecival has retired from the superintendency of the Cook County institutions, Dunning; the institutions are at present under the care of Dr. Carl F. W. Eberlein, assistant physician.——Dr. Chauncey Sherrick has been made chairman and Dr. Edward L. Mitchell a member of the committee of arrangements for the dedication of the new Monmouth Hospital.

Money for Children's Home.—It is announced that James A. Patten, Evanston, has donated $10,000 toward the purchase of a building for the Frances Juvenile Home Association, Chicago. The object of the home is to care for children afflicted with contagious or infectious diseases, and is intended to supplement the work of Cook County Hospital. The capacity of the home at present is fifteen, but the plans contemplate the accommodation of two hundred patients.

Conference of Charities and Correction.—The sixteenth annual State Conference of Charities and Correction will be held in Urbana, Ill., October 21 to 24. The social hygiene section will hold a mass meeting in the University of Illinois auditorium Sunday afternoon, at which Drs. Woods Hutchinson, New York, and George F. Butler, Chicago, and Mrs. Albion Fellows Bacon of Indiana will speak. In the evening Dr. Charles Henderson of the University of Chicago will deliver the conference address. Monday afternoon the county farm superintendents will hold a meeting, presided over by Mr. William C. Graves, formerly secretary of the Illinois Board of Charities: at the superintendents' meeting in the evening Hon. L. Y. Sherman, president of the State Board of Administration, and Chief Justice Harry Olson of the Chicago Municipal Court will speak. The exhibits are expected to be on a large scale.

Chicago

Personal.—Dr. F. Curt Harnisch sailed for Europe August 22.——Dr. Alexander H. Ferguson, who has been seriously ill, is reported to be improving.——Dr. Charles F. Yerger was operated on recently and is reported to be doing well.——Dr. I. S. Trostler has taken charge of the *x*-ray laboratory of St. Joseph's Hospital.——Dr. B. Barker Beeson has returned from Europe.

New Sanitarium.—One hundred and sixty acres of land has been purchased west of Rose Hill Cemetery, for the new municipal tuberculosis sanatorium, on the building and grounds of which about $1,000,000 will be expended. Harlow N. Higginbotham is chairman of the committee which has the matter in charge. The law under which the sanatorium is being erected empowers any municipality in the state to raise funds for such purposes, if the people by referendum vote so decide.

Industrial Care of Tuberculosis.—The Chicago Tuberculosis Institute in its August bulletin calls attention to the efforts made by the institute during the last two years to interest large employers of labor in the physical examination of their employees with a view to reducing the amount of tuberculosis. The firm of Sears, Roebuck & Co. erected a six-bed cottage at the Edward Sanitarium, Naperville, about two years ago, for the care of their employees suffering from tuberculosis. At the same time they put into practice a system of examination for all employees who showed traces of the disease.——Montgomery Ward & Company built a model six-bed open-air cottage at the same institution for the care of their employees.——The International Harvester Company has adopted the plan of Dr. Theodore B. Sachs for the systematic examination of employees in manufacturing establishments. The list of suspected tuberculosis patients will include employees in whom the diagnosis of tuberculosis has previously been made; employees whose poor general condition, in connection with other suspicious symptoms suggest the presence of the disease; employees with histories of protracted cough and expectoration and employees in whose families tuberculosis exists, or in which a death from the disease has recently occurred. Dr. James A. Britton and Miss M. J. Flannagan have been placed in charge of the special tuberculosis clinic to be inaugurated for the benefit of the employees of the company. The institute announces that it is now ready, through its advisory committee, to act in an advisory capacity with other large employers of labor to secure a more general adoption of the plan proposed.

INDIANA

Isolation Hospital for Military Post.—The War Departmen has ordered that an isolation hospital be established at Fort Benjamin Harrison, near Indianapolis.

Daily Bulletin.—The City Board of Health of Indianapolis has begun the publication of a *Daily Bulletin,* touching on health subjects; thus far bulletins on care of infants, sewage, garbage cans and house flies have been issued.

State Association Meeting.—The meeting of the Indiana State Medical Association will be held in Indianapolis, September 28 and 29, under the presidency of Dr. Frederick C. Heath, Indianapolis. United States Senator Robert L. Owen of Oklahoma, and Dr. William Welch of Johns Hopkins University, are announced as special speakers on the program.

Personal.—The farm home of Dr. Simon P. Scherer, near Noblesville, was destroyed by fire August 10, the loss amounting to about $9,000.——Dr. Hugh T. Montgomery, the oldest practitioner of South Bend, announces that he will soon retire.——Dr. Charles S. Goar, Indianapolis, who has been ill for several months as a result of an automobile accident, is reported to have recovered sufficiently so that he can take out-door exercise.

Health Officers' Authority Limited.—The Attorney-General of Indiana has given an opinion to the State Board of Health at the request of Dr. Eric A. Crull, health officer of Fort Wayne, that a health officer in the absence of an ordinance giving him such powers is not vested with the authority of a police officer. Dr. Crull desired to know whether he has the right to go out and make arrests for violation of the health laws or whether he should depend on the police.

Increase in Poliomyelitis.—Infantile paralysis increased markedly during the month of July, thirty-seven cases having been reported to the State Board of Health. The secretary of the board is in communication with the State Board of Health of Illinois in an endeavor to locate the origin of the epidemic. The focus last year was Fowler, Ind., from which several cases have been reported this year, with a spread of the disease in a southeasterly direction. Shelby County hogs have been afflicted with a similar disease and in Carroll County a cow had the same symptoms. The Rockefeller Institute has been asked to carry on experiments in regard to the transmission of the disease from animals to man.

Sanitary Survey.—The State Board of Health is conducting a sanitary survey of the region along the Ohio River on account of the increased amount of disease in that vicinity. Statistics show that the death-rate is higher along the Ohio River than in the interior of the state, due to the amount of typhoid fever. In the town of Rockport the highest death rate is shown, which is 34.4 deaths per 1,000. The death-rate from typhoid alone at Vevay is 134 per 100,000. The Ohio River from the Ohio line to Louisville shows fecal contamination. From the examination of samples of well water, shallow wells, taken from widely scattered communities throughout the state, Dr. Barnard, the State Food and Drug Commissioner, asserts that fully 50 per cent. of the shallow wells in Indiana are polluted and impure for drinking purposes. White River, which flows through Indianapolis, is polluted by sewage. The mayor is cooperating with the city board of health in an effort to establish a municipal sewage disposal plant.

MARYLAND

Personal.—Dr. Charles H. Diller, Detour, was operated on for disease of the intestine, August 23.——Dr. James M. Goodman, Frederick, had a man arrested for blocking the road and not allowing him to pass while on his way to see a patient. The man was held under $50 bonds to the grand jury.——Dr. James L. McCormick, Trappe, has been adjudged insane and committed to the Springfield State Hospital.

Baltimore

Herter Lectures.—The annual Herter Lectures will be delivered October 4, 5 and 6, by Prof. Dr. Albrecht Kossel of t University of Heidelberg, who was awarded the Nobel pri last year for important discoveries in medical chemistry.

Personal.—Capt. Robert P. Bay, M.C., N.G., Md., assigned Fifth Infantry, has been made chief surgeon with rank of major, and assigned to the First Brigade, vice Maj. Alexius W. McGlannan, resigned.——Dr. Gustav A. Thiede has been appointed a health warden vice Dr. George B. Scholl, resigned.——Dr. George Heller has recovered from his recent severe illness.

MISSOURI

Headquarters Established for Tuberculosis Society.—The uchanan County Society for the Relief and Prevention of Tuberculosis has established permanent headquarters at 2137 South Sixth Street, St. Joseph, where reports will be received, or information may be obtained, regarding the treatment of tuberculosis.

Personal.—Dr. M. C. Stone, Kansas City, has been appointed state bacteriologist to succeed Dr. Newton McVey.——Dr. Albert H. Myerdick, formerly city dispensary physician of St. Louis, has been appointed physician to the State Penitentiary at Jefferson City, succeeding Dr. James A. Waterman, who has been recently appointed superintendent of State Hospital No. 4, Farmington.——Dr. Price, assistant physician at State Hospital No. 3, Nevada, has resigned and will practice in Independence.——Dr. J. R. Van Atta has been appointed pathologist to the Kansas City General Hospital, vice Dr. M. C. Stone.——Dr. Albert B. Stone, Lamar, has been appointed a member, and elected secretary, of the Barton County Board of Health.

Hospital Staff Named.—The following medical and surgical staff is announced for the Kansas City General Hospital, for the year beginning September 1: superintendent, Dr. Louis W. Luscher; attending surgical staff, Drs. Jabez N. Jackson, John F. Binnie, John M. Frankenburger, Hermann E. Pearse, Jefferson D. Griffith, Howard Hill, Ernest F. Robinson and William D. Foster; attending medical staff, Drs. John L. Robinson, Charles C. Conover, Robert T. Sloan, Frederick McK. Lowe, Franklin E. Murphy, Hugh D. Hamilton, Arthur C. Leonard and Scott P. Child; consulting staff: pediatrics, Drs. Clay S. Merriman, Frank C. Neff and Jesse E. Hunt; orthopedics, Drs. C. B. Francisco and Robert McE. Schauffler; gynecology, Drs. George B. Norberg and C. Lester Hall; otology and laryngology, Drs. Flavel B. Tiffany, Andrew W. McAllester, Jr., and Joseph S. Lichtenberg; dermatology, Drs. Halsey M. Lyle and William Frick; neurology, Drs. John Punton and Henry O. Hanawalt; attending physician, Dr. G. Wilse Robinson; assistant attending physician, Dr. Rush E. Castlelaw; skiagraphy, Drs. Edward H. Skinner and Oliver H. McCandless; obstetrics, Drs. Caleb A. Ritter and George C. Mosher; genito-urinary diseases, Drs. Ernest G. Mark and F. M. McCallum; pathologists, Drs. William K. Trimble and Edward L. Stewart; oral surgery, Dr. Harold P. Kuhn, and dentists, Drs. W. T. Stark and H. B. McMillan.

NEW YORK

Changes at Matteawan.—Dr. James V. May, the newly appointed superintendent of the Matteawan State Hospital for the Criminal Insane, assumed charge of the institution August 14.——Dr. Raymond F. C. Kieb, first assistant physician at the Dannemora State Hospital, has been appointed temporarily as first assistant physician at Matteawan.——Dr. Dr. John W. Russell, for sixteen years a member of the staff of the Willard State Hospital, has been appointed assistant physician at Matteawan.

To Prosecute Cold Storage Men.—Following investigations made by state inspectors in the larger cities the State Health Department has made public a statement that there are millions of pounds of butter, eggs, poultry and fish held in cold storage beyond the limited time and in a condition unfit for food. The Brennan Cold Storage Law, in addition to limiting the time during which food may be kept in cold storage, provides that food once exposed for sale shall not be restored and that all storage food must be labeled with the date of its receipt in storage and of its delivery therefrom, and that when sold, it shall be represented as cold storage food. The most flagrant violations of this law have been found in New York, Syracuse, Albany, Utica, Rochester and Buffalo. The offenders will be prosecuted and the State Department of Health will use all its powers to see that the law is enforced in the future.

New York City

Addition to Hospital.—The new addition to the Margaret Fahnestock Training School of the New York Post-Graduate Medical School and Hospital is completed, and the building now provides accommodation for 139 nurses.

Cholera Steamer in New York Harbor.—Cholera caused three deaths on the steamer *Re d'Italia* which arrived from Naples and Palermo, August 17. Two other passengers in the hospital show signs of the disease. The steamer is detained in quarantine, pending examination of the passengers.

Work of the Diet Kitchen Association.—This association has more than 1,500 babies under its care and has dispensed as much as 24,650 quarts of milk in a week. It supports nine milk stations and renders efficient help to the board of health. There has been practically no mortality among the babies cared for by this organization this summer.

Ridding City of Stray Animals.—The Society for the Prevention of Cruelty to Animals has been busy since June 1 gathering up homeless cats and dogs. During a single night as many as 866 cats have been captured. Since August, 12,500 have been caught and since the beginning of the work 113,186 animals have been collected. It is generally admitted that cats may be carriers of disease and the crusade has seemed necessary on this account.

No Public Cups After October 1.—A new sanitary code ordinance will go into effect on October 1, which abolishes drinking cups in all public places, public schools, railroad stations and theaters. School children will have to furnish their own cups and it will be considered a violation of the law for any person to loan his or her cup to another. In order to assist in this movement a large department store is making a free distribution of several hundred thousand pocket drinking cups to school children.

Personal.—Dr. H. C. Cohen, ambulance surgeon of the J. Hood Wright Hospital, suffered a dislocation of the shoulder and serious injuries of the head and face in a collision between the ambulance on which he was riding and an Amsterdam Avenue car.——Drs. William Linder and O. Kruskal, Brooklyn, have returned from Europe.——Dr. Frederick L. Flynn, Bronx, Brooklyn, was injured August 19, in a collision between his automobile and a milk wagon.——Dr. Hoffman, ambulance surgeon at the Bellevue Hospital, was injured in a collision between his ambulance and a street car, August 23.

The Typhoid Situation.—For the week ended August 26, sixty new cases of typhoid fever were reported in the Borough of Manhattan as against eighty-eight for the previous week. In the Bronx there were thirty-one new cases reported as against forty-seven for the previous week. During the past month there have been thirty-five cases reported from the Roman Catholic Asylum in the Bronx. The investigations of the health department seem to indicate that the milk and water-supply cannot be held responsible for the outbreak in the Bronx, and that it is probable that flies and mosquitoes have been instrumental in spreading the infection. Some of the cases in Manhattan have been traced to the milk supply.

Hospitals Under New Charter.—The proposed new charter for the city of New York provides for the transfer of Bellevue and the Allied Hospitals from the present trustee system to a commission to be appointed by the mayor. This would be a reversion to the old state of affairs and the condition of the hospitals is so much better under the present system that there is much opposition to this proposed change. At a recent hearing on this phase of the charter many charitable and philanthropic organizations appeared against the change but no one spoke in its favor. Representatives of some of these charities urge all who are interested in the welfare of the sick poor or in the hospitals to use their efforts to obtain the defeat of this provision at the coming session of the legislature.

NORTH DAKOTA

Personal.—Dr. Arthur A. Husser, Berthold, fractured two ribs and sustained serious bruises in an automobile accident near his home August 20.——Dr. Benjamin R. McAllister, superintendent of the State Hospital, Jamestown, has resigned and will practice at his old home at King City, Mo.

PENNSYLVANIA

State Meeting.—The Medical Society of the State of Pennsylvania will hold its annual convention in Harrisburg, September 25 to 28, under the presidency or Dr. John Boyce Donaldson, Canonsburg.

Making Progress on Sanitarium.—More than 100 men are now employed on the State Tuberculosis Sanitarium at Creson, and the first building, the dining hall, is now nearly completed. It is a two and a half story structure in the form of a Maltese cross. The east ward, administration building and power plant are also in course of construction.

Philadelphia

Bequest.—The executors of the estate of Max Bamberger have sent $10,000 to the Jewish Hospital Association and $5,000 to the Jewish Foster Home and Orphan Asylum.

Cholera Suspects.—The North German Lloyd Steamship Brandenburg from Bremen, arrived at Philadelphia, August 23, and was placed in quarantine because of a case of suspected cholera in a second cabin passenger.

Addition to Hospital.—Plans are being prepared for a three-story addition to the Northwestern General Hospital. The annex is to be in the rear of the present hospital building and will contain a dispensary, an operating room and private rooms.

Typhoid Traced to Milk.—The report of contagious diseases to the health department gives a total of fifty-eight typhoid fever cases, of which five were reported from the Twenty-second ward and nine from the Thirty-second ward. These were traced to milk infection and steps have been taken to cut off the supply of infected milk.

Memorial Tablet Unveiled.—A bronze tablet, to mark a bequest by the late Mrs. Estelle P. Melville, wife of Rear Admiral George W. Melville, was unveiled in the women's ward of the Episcopal Hospital on August 21. The tablet bears the following inscription: "Comfort the Sick. In memory of three sisters—A. V. Palis Truitt, Melina Palis and Estelle Palis Melville." The bequest endowed three beds in the ward.

City Babies for Adoption.—The children's wards of the Philadelphia General Hospital are so overcrowded that Dr. Joseph G. Neff, Director of the Public Health and Charities, has advertised in the German and Italian newspapers of the city for foster mothers, who will receive $3 per week and carfare for a certain period. Each woman will be obliged to report weekly with the child after it has been placed in her care and both will be examined.

Gift of Gymnasium.—Jacob Disston, who recently donated the site of the old Disston residence at Tacony to the city of Philadelphia for use as a public playground, has made an additional gift of $10,000, which will be utilized in making a model playground, erecting an up-to-date gymnasium, the construction of which was begun August 24. The building is to be of brick. two stories in height, 40 by 40 feet, with two one-story wings, 29 feet 6 inches by 33 feet.

Infant Mortality Declines.—Nearly one-third of the deaths of the city for the week ending August 26 were of children under 2 years of age. The total number of deaths was 464 and the total of children under 2 years was 149, of which 104 died of enteritis. But despite these figures the infant mortality in the city for the first three weeks of August was reduced 36 per cent., as compared with the corresponding period of last year. This is accounted for by the fact that the milk supply has been greatly improved by refrigeration in transportation, by better equipment of hospitals and by the city's corps of visiting nurses. In the first three weeks of August, 1910, there were 688 deaths of children under 5 years and in the same period of this year there were 434.

Personal.—Drs. Penn Gaskell Skillern and William W. Keen have sailed for Europe.——Dr. John F. McCloskey was badly injured in an automobile accident on August 18.——Dr. Herbert A. Bolan, who sustained a concussion of the brain from a fall, August 22, is recovering.——Dr. Gertrude A. Walker has recently given to the hospital connected with the Women's Medical College of Pennsylvania $1,000 for the endowment of a baby's crib in the College Maternity.——Dr. Herbert A. Bolan suffered a cerebral hemorrhage August 21, and was taken to the Presbyterian Hospital.——Dr. John F. McCloskey had three ribs broken and sustained severe contusions and scalp wounds when his automobile ran into a fallen tree, near Philadelphia, August 19.

WASHINGTON

State Meeting.—The annual meeting of the Washington State Medical Association will be held in Spokane, September 7, 8, 9, under the presidency of Dr. Wilson Johnston, Spokane. A public meeting is to be held under the auspices of Dr. J. B. Anderson, city health officer.

Personal.—Dr. George T. Boyd, Palouse, fractured his right arm, August 2, while cranking his automobile.——Dr. Frank A. St. Sure, formerly of Madison, Wis., has been appointed surgeon for the Chicago, Milwaukee and Puget Sound Railway at Ellensburg.——Dr. William L. Hall, Spokane, who recently fractured his ankle, is recuperating at his orchard home in Green Bluff Prairie.

Antituberculosis Association Election.—At the annual meeting of the Washington Association for the Prevention and Relief of Tuberculosis the following medical men were elected to office: president, Dr. Christen C. Quevli, Tacoma (reelected); vice-president, Dr. Wilson Johnson, Spokane; secretary, Dr. Walter C. Lippincott, Seattle; and directors the president and Drs. James R. Yocom, Tacoma; William S. Durand, Everett; Cornelius J. Lynch, North Yakima; Edward B. Nelson, Spokane; William C. Cox, Everett; James Sutherland, Spokane; Elmer E. Heg, Seattle; Eugene R. Kelley, Seattle, and Dr. Lee M. Ganson, Odessa.

GENERAL NEWS

Missouri Valley Physicians to Meet.—The twenty-fourth annual meeting of the American Academy of Ophthalmology ley will be held in Omaha, September 7 and 8, with headquarters at the Rome Hotel, under the presidency of Dr. Donald Macrae, Council Bluffs, Ia.

Eye, Ear and Nose Specialists to Meet.—The sixteenth annual meeting of the American Academy of Ophthalmology and Oto-Laryngology will be held in Indianapolis, September 25 to 27, with headquarters at the Claypool Hotel, under the presidency of Dr. John J. Kyle of Indianapolis. Dr. Albert Gray of Glasgow, Scotland, will be the guest of the academy.

Pathologists and Nurses Wanted for Philippines.—The United States Civil Service Commission, Washington, D. C., will send to those interested circulars concerning vacancies. To a bacteriologist and pathologist at Manila a salary of $2,000 is offered. An examination will be held September 23. The same commission desires trained nurses for the Philippines and the Indian Service.

Meeting of Pure Food Departments.—At the annual convention of the Association of State and National Pure Food Departments, held in Duluth, Minn., August 21 to 24, Seattle was chosen as the site of the next meeting, and a telegram expressing confidence in Dr. Harvey W. Wiley, and promising support of his official acts was ordered sent to the President. The following officers were elected: Lucius P. Brown of Tennessee, president; H. E. Barnard, C. H. Billingsby and Joel G. Winkjer, Jr., vice-presidents; W. M. Allen, secretary; James Faust, treasurer; and Edwin De Barr, and Dr. Samuel J. Crumbine, Topeka, Kan., and Dr. Charles D. Woods, executive committee.

International Municipal Congress.—The preliminary program of the International Municipal Congress and Exposition to be held at the Coliseum in Chicago, September 28 to 30, announces the following general subjects for discussion: September 28, morning, "Methods of Controlling a Milk Supply;" afternoon, "Control of Contagion and School Inspection;" September 29, morning, "Protection of Water and Disposal of Sewage;" afternoon, "Yard Sewage and Slaughter Houses;" evening, "The Law in Relation to Health Work;" September 30, morning, "Disposal of Garbage;" evening, "Cost of Health Department Per Capita." Dr. William A. Evans, former health commissioner of Chicago, has been appointed chairman of the Health and Sanitation Division of the congress.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Aug. 18, 1911.

The Sanitary Situation with Regard to Cholera

During the last session of the permanent commission of the superior council of hygiene, which was held a few days ago under the presidency of Dr. Roux, director of the Pasteur Institute, M. Mirman reported the sanitary situation with regard to cholera. He emphasized especially the fact that aside from some isolated cases which have occurred in the departments of Bouches-du-Rhône and l'Hérault (THE JOURNAL, Aug. 19, 1911, p. 667), no case of cholera has appeared in France, notwithstanding various recent reports in the papers, which may be due to the instructions issued by the government that every case of choleriform diarrhea shall be examined and treated as a suspected case of cholera. Cases of choleriform diarrhea are particularly numerous this season, and the newspapers, judging from imperfect information, have concluded that these cases were cholera. The commission passed a resolution that all possible means of publicity be used to remind the public, in all cities where cases of summer cholera appear, of the utility of boiling water for drinking and of eating vegetables only when cooked and of taking all precautions of individual hygiene.

Moreover, as a precaution, the minister of the interior has just prohibited the pilgrimages to Lourdes. The sanitary situation in l'Hérault where Lourdes is situated has, however, become satisfactory. The epidemic has disappeared and the few cases reported during the last few days are progressing toward recovery. At present there is only one epidemic focus, which is that at the insane asylum at Marseilles, but there the conditions make isolation as effective as possible.

Dr. Doyen and Foot-and-Mouth Disease

For some time an epidemic of foot-and-mouth disease has been raging in several departments, owing to the reluctance of cattle owners to report cases and to isolate the affected animals. Dr. Doyen has made use of this occasion to seek notoriety once more. Unfortunately Dr. Doyen is not content with the deservedly high reputation which he enjoys as a skilful surgeon, but periodically breaks forth in the daily papers with sensational accounts of miraculous cures that he alleges he has obtained in all kinds of infectious diseases and in tuberculosis especially by the employment of a certain *solution phagogène* of his own preparation. From the beginning of the present epidemic of foot-and-mouth disease Dr. Doyen has been asking from the minister of agriculture letters to the prefects of the infected departments authorizing him to carry on treatment of foot-and-mouth disease by his *solution phagogène*. The minister of agriculture complied and Dr. Doyen, after having carried on a series of experiments, has addressed an open letter which is of course reproduced in all the daily papers, in which he declares that "foot-and-mouth disease is definitely conquered" and that the application of his treatment "is going to end infallibly in the revision of the rules of the sanitary police." At the same time with this letter, however, there were received at the ministry of agriculture reports from the presidents of the agricultural committees and letters from farmers stating that the results obtained by Dr. Doyen, although satisfactory in part, ought to be received with much reserve. The agricultural department, therefore, has thought it best to publish a note declaring that Dr. Doyen's results are not yet sufficiently attested and that until the efficacy of his treatment has been well established by methodical experiments it would be imprudent to relax the strictness of our sanitary legislation in respect to foot-and-mouth disease.

Abdominal Pneumococcic Septicemia

At the last session of the Société médicale des hôpitaux de Paris, Dr. Triboulet drew attention to the fact that while pneumonia, in the child as in the adult, represented the spontaneous and relatively benign fixation of the pneumococci, the case is quite different when the pneumococcic septicemia is localized in the abdomen. In addition to severe diarrhea, a duodenal catarrh (bilious diarrhea) is noticed which is particularly frequent in serious and prolonged cases with or without complications (otitis, purulent pleurisy, etc.). A diarrhea may also be associated with the peritoneal syndrome from the beginning, the diagnosis being uncertain and the symptoms recalling appendicitis or typhoid fever. Such cases demand continued treatment by colloidal silver. The patients, moreover, should be watched for a long time for the possibility of some development demanding surgical operation. These observations were confirmed by Dr. Caussade. The possibility of pneumococcus septicemia should be kept in mind in forming a diagnosis, since it is much more frequent than is generally believed.

The Rôle of the Nervous System in the Pathogenicity of Arteriosclerosis

Arteriosclerosis during the last two years has been the subject of a great number of experimental researches, but there has been no inquiry into the possible agency of the nervous system in causing these arteriosclerous lesions. On this subject M. Y. Manouélian recently made an interesting report to the Académie des sciences. He first divulsed a nerve fiber arising at the level of the solar plexus and running to the abdominal aorta in dogs and killed the animals at the end of a period varying from twenty days to two months. At the autopsy he found sclerous plaques in the region of the aorta corresponding to the nerve fiber divulsed, the rest of the aorta remaining absolutely unaffected. Another experiment consisting in divulsing a large nerve fiber running into the pulmonary artery after opening the thorax and making an incision in the pericardium. The dog having been killed sixty-five days after this operation, the autopsy showed a sclerous plaque in the region corresponding to the nerve fiber removed. Manouélian concludes that nervous lesions play an important rôle in the production of arteriosclerosis.

A Resolution with Regard to Criminals Acquitted on the Ground of Irresponsibility

At the close of the last session of the assizes of the Seine, the jury which had just acquitted a murderer on the ground of irresponsibility, sent to the minister of justice a note communicating a resolution, signed by twenty-eight of the thirty-one members of the jury, that the law should permit criminals acquitted on the ground of irresponsibility to be shut up in a special sanatorium until they ceased to be a danger to the public.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Aug. 11, 1911.

Personal

Professor Stähelin, first assistant at the Berlin Medical Clinic I, has been appointed director of the medical clinic at Basel, succeeding Professor Gerhardt. Professor Sauerbruch of Zurich has been appointed director of the surgical clinic at Königsberg, which position was refused by Professor Enderlen of Würzburg. Professor Trendelenburg, in Leipsic, who, as I have written already, resigned at the end of this semester, has received the title of privy councilor, with which is connected the title of *Excellenz.*

Professor Dr. Levy of Strassburg, the former assistant of Professor Foster, has received an extraordinary professorship in social hygiene. Professor Passow, the director of the Berlin Ear Clinic, has obtained an extraordinary professorship in rhinology. It is evident that this is meant to be a consolation for Passow's failure to obtain the management of the laryngologic clinic, to which position he aspires.

Unusual Jubilee

August 6, Privy Sanitary Councilor Friedrich Körte celebrated a very unusual jubilee, the seventieth anniversary of his doctorate. Körte, who is the father of the well-known surgeon, has for many years occupied a prominent position in Berlin medical circles. When only a young man he was elected president of the Gesellschaft für wissenschaftliche Medizin, a proof of his high repute among colleagues. Later, he succeeded in uniting this society with the Gessellschaft Berliner Aerzte (founded by Albrecht v. Gräfe) to form the Berliner medizinische Gessellschaft. Körte was president of this sociey, and was later succeeded by his friend Rudolf Virchow. In the professional life of Berlin, Körte was for a long time a leading figure. When in 1887, in Prussia, the Aerztekammer was founded as a professional representation, Körte was the first president of the Berlin Aerztekammer. Now, at the age of 93, he enjoys comparatively good health, physically and mentally.

Conflict Between Physicians and Krankenkassen

In Halle a conflict has broken out between the physicians and the Krankenkasse organization, the former demanding a family insurance and also the free choice of physicians. The central meeting of the Krankenkassen rejected the propositions, as it was claimed to be impossible to pay the total sum of 10 to 12 marks ($2.50 to $3.00) for each insured individual.

The Warfare Against Sleeping-Sickness

As reported, the chief of the colonial health-board, Professor Dr. Steudel, has just left Marseilles for German East Africa where he will pursue the study of sleeping-sickness. The route is from Mombassa via the English Uganda railroad to Lake Victoria, where an inspection of the sleeping-sickness camps along the eastern shore will take place. From here Dr. Steudel will travel to Muansa, by the same lake, this point offering special interest, being an endemic seat of the disease. In Bukoba, also by the lake, will be visited the two oldest of sleeping-sickness camps in German East Africa, which have existed since 1907. Thence the journey will continue to Kissenji, by Lake Kiwu, from the south end of which the road goes through the Russisi Valley to Usambara, at the northern end of Lake Tanganyika, the government seat of Urundi. The Russisi Valley is of especial interest because it is the main road from Tanganyika, from which direction the disease is spreading; for protection much timber has been cleared here. Six sleeping-sickness camps will be visited at the northern end of Tanganyika where the disease claims the most victims in the German territory. From Ujiji, the terminal point of the East African Central Railroad, the journey will lead over Tabora to the angle of the road and then with the Central Railroad, as far as it is completed, back to Daressalam. Thus, the hygienic conditions along the railroad as well as in the capital, Daressalam, will be studied; especially the preventive measures against malaria will be tested. A visit is planned to the high altitude sanatorium Wugiri and perhaps also to the settlement at Kilimanjaro. The trip is planned to last about five months.

Infant Mortality in the Large Cities

According to statistics compiled at Amsterdam, that city has the lowest infant mortality among twenty large European cities, namely 8 per 100 births. Next comes Paris with 9 per cent.; third, London with 10.2 per cent.; and fourth, Milan with 12.4. The highest figures are furnished by Moscow, 32.6 per cent., and St. Petersburg, 25 per cent; then follows Breslau with 20.7; Munich, 19.2; Leipsic, 17.2; Vienna 16.4; Budapest 16.2; Berlin 14.6; Hamburg, 13.8; Dresden 13.3, after which follow Rome, Naples, Manchester, Liverpool, Birmingham and Glasgow. As a whole, the infant mortality in the twenty cities during the last three decades has decreased as follows: In Munich from 36.9 to 19.2; in Breslau from 35.0 to 20.7; in Berlin from 31.3 to 14.6; in Dresden from 24.3 to 13.3; but in Moscow only from 34.6 to 32.6; in St. Peterburg from 29.9 to 25.0; in Vienna from 18.8 to 16.4; in Rome from 18.8 to 13.4; in London from 15.8 to 10.2; in Paris from 18.4 to 9.4, and finally, the very remarkable decrease in Amsterdam, from 24.5 to 8.0 per 100 births.

Miscellany

The Hemoleukocytic Formula in Human Tuberculosis.—The investigation of the changes which the blood undergoes in consumptives has given rise to many studies, and their authors have come to such divergent conclusions that up to the present it has been impossible to establish a well-defined hemoleukocytic formula which might serve as a standard for instituting a more or less exact hematologic diagnosis, as in the case of other diseases. Tuberculosis is a disease which develops between periods of calm and of exacerbations more or less intense, and it is precisely in these intervals that the infection progresses and changes its phases, so that if, in addition to the clinical observation, a repeated examination of the blood is also made, a type of hemoleukocytic desequilibrium may be established which will permit useful deductions to be made respecting the course of the infection, the reactional energy on the part of the organism, the therapeutics and even the provisional prognosis. Following these ideas M. Dominguez (*Sanidad y Beneficencia*, April, 1911) made an attempt to study the question. He has been able to follow thus *far the* course of forty observations, including adults and children in various stages of the disease. The greatest possible amount of data in relation to the phases of the infection has been obtained, and note of the clinical symptoms has been taken
[illegible] making the analysis of the blood. In all patients the
Cuba, Ill. of the Koch bacillus in the sputum was confirmed.
Frederick A[illegible]ained from the globular count in his cases were
of Chicago, July 26. of red cells per cubic milli[illegible]
with hemopt[illegible]
medium-sized cells predominating. Persistent lymphocytosis in closed coxalgias was notable, the figure varying between 31 and 40 per cent. Large mononuclears varied between .62 and 15.67 per cent., the most constant figures being from 9 to 12 per cent. In a general way, therefore, Dominguez finds that unadvanced consumptives with small hemorrhages, with fever and scant expectoration and tendencies to regression, present a leukocytosis of 9,000 to 12,500, a low mononucleosis of 12 to 15 per cent., and an eosinophilia which at times reaches over 5 per cent. when the manifestations cease and which maintains itself more or less in relation to the period of apparent recovery. In the laryngeal forms there is a lymphocytosis of between 25 and 35 per cent. In tuberculous coxalgias in children, there is a slight or no hypoleukocytosis, 37 to 55 per cent. polynuclears, and 4 to 8 per cent. polynuclear eosinophilia, the characteristic of these forms being the lymphocytosis, at times reaching 46 per cent.

Prophylaxis of Epidemic Poliomyelitis in Norway.—The authorities in Norway published in June an appeal to physicians to be on the lookout for acute poliomyelitis, saying that it has recently appeared at different points throughout the country and the number of cases and the virulence of the disease as observed now surpass all experiences since the epidemics of 1905. After referring to the circul[illegible]
the authorities in 1904, the [illegible] College of Physicians and Sur-
the necessity for [illegible]isa, 1880; a member of the Teller County
during th[illegible]ociety; died in Victor, Colo., July 17, seven days
after an operation for appendicitis, aged 55.

Deaths

Charles Voorhees Butler, M.D. New York University, New York City, 1893; of New Brunswick, N. J.; a member of the American Medical Association; a member of the staff of St. Peter's Hospital, New Brunswick, and Wills Memorial Hospital, Philadelphia; acting assistant surgeon, U. S. Army, during the Spanish-American War; died in Paris, France, July 15, from septicemia following a carbuncle, aged 42.

Herman P. Bender, M.D. University of Freiberg, Germany, 1879; a member of the Medical Society of the State of New York; a well-known surgeon of Brooklyn; radiographer to the German Hospital and president of its medical board, and also a member of the staff of Kings County Hospital; while alighting from a trolley car in Brooklyn, August 15, was struck by a speeding automobile and instantly killed, aged 54.

Guy Abbott Grafton, M.D. University of Minnesota, Minneapolis, 1899; of Hayward, Wis., formerly of Winona, Minn.; a member of the American Medical Association; died in St. Joseph's Hospital, Ashland, Wis., August 9, from acute peritonitis, following fracture of the leg in an automobile accident, a week before, aged 34.

John Henry Korff, M.D. College of Physicians and Surgeons, New York City, 1869; formerly a specialist on diseases of the eye and ear of New York City, and later an employee of the U. S. Subtreasury, Manhattan; died at the home of his son in East Orange, N. J., August 16, from cerebral hemorrhage, aged 67.

Edward O. Gratton (Years of practice, Illinois, 1878) hospital steward and acting assistant surgeon U. S. Army, assigned to the Seventy-Second Illinois Volunteer Infantry during the Civil War; a member of the first Board of Trade of Chicago; died at his home in Harvard, Ill., August 18, *aged* 84.

Edward Bernard Coburn, M.D. Albany (N. Y.) Medical College, 1890; a member of the Medical Society of the State of New York and the New York Academy of Medicine; surgeon to the New Amsterdam and Cornell dispensaries; died at his home in New York City, August 10, aged 43.

Patrick R. Bailey, M.D. University of Nashville, Tenn., 1868; a Confederate veteran; for thirty-four years an employee of the United States postal service; head of the mailing division of the Nashville Post Office; died at his home in Nashville, August 16, from heart disease, aged 64.

Benjamin Wilson, M.D. College of Physicians and Surgeons, New York, 1863; a member of the American Medical Association; surgeon of U. S. Volunteers during the Civil War; died at his home in Rochester, N. Y., August 13, aged 71.

John T. Kennedy, M.D. Tulane University, New Orleans, 1868; for more than twenty years vice-president of the Fannin *County* (*Tex.*) National *Bank*; died at his home in Bonham, August 17, from heart disease, aged 71.

Quincy Adams Lowe, M.D. Long Island Hospital College, Brooklyn, 1873; a veteran of the Civil War; for twenty-six years a practitioner of Crookston, Minn.; died at his home in Riverdale, Cal., August 5.

Ralph N. Gordon, M.D. University of Michigan, Homeopathic College, Ann Arbor, Mich., 1897; for thirty-five years a practitioner of Arlington, Ill.; died at his home in Seattle, Wash., August 7, aged 69.

Lewis Almon Harmon, M.D. Grand Rapids (Mich.) Medical College, 1905; of Marshall, Mich.; died in a hospital in San Antonio, Tex., August 10, shortly after an operation for acute peritonitis, aged 34.

Exeter P. Vaux, M.D. University of Louisville, Ky., 1876; a member of the Medical Society of the State of California; died at his home in Santa Cruz, April 14, *from* cerebral hemorrhage, aged 59.

William Joseph Mason, M.D. Atlanta (Ga.) Medical College, 1884; of Riderville; a member of the Medical Society of the State of Alabama; died at Selma, in July, from nephritis, aged 50.

Samuel Reed Richey (license, Indiana, 1897); died at his home in Donaldson, *Ind.*, August 1, from ulceration of the pylorus, complicating chronic gastro-intestinal catarrh, aged 70.

James J. Gleeson, M.D. University of Pennsylvania, Philadelphia, 1898; of New Haven, Conn.; died in St. Raphael's Hospital in that city, August 12, from pneumonia, aged 36.

Samuel O. Moore, M.D. University of Louisville, Ky., 1886; of Winnsboro; a member of the State Medical Association of Texas; died at Mineral Wells, Tex., August 16, aged 54.

Michael John Crilley, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1869; of Prescott, Ariz.; a veteran of the Civil War; died in Foster, O., August 13, aged 64.

Patrick J. Byrne, M.D. Bellevue Hospital Medical College, 1888; a *member* of the American Medical Association; died at his home *in Bronx Borough*, New York, August 3.

Alphonso Armstrong, M.D. Medical College of Ohio, Cincinnati, 1871; died recently at his home in Kewanna, Ind., from heart disease, *aged* 67.

Snowden Robertson, M.D. Atlanta (Ga.) Medical College, 1873; died at his home in Dallas, Ga., May 31, from cerebral hemorrhage, *aged* 71.

Morse Stewart, M.D. Detroit (Mich.) Medical College, 1878; of Petite Côte, Que.; died in the Hotel Dieu, Windsor, Ont., August 10, aged 58.

Edward R. Tevis, M.D. Louisville (Ky.) Medical College, 1880; died at his home in Brooksburg, Ind., June 30, from uremia, aged 55.

The Malarial Cycle.—Reviewing Professor Ross' "Prevention of Malaria," E. A. Minchin says in *Science Progress* that "the malarial theorem, as Ross aptly terms it, may be stated briefly as follows: Malaria in man or animals is a disease caused by a minute parasite which lives and multiplies in the blood, passing its trophic phase within the red blood-corpuscles. The parasite is propagated from one vertebrate host to another by the agency of certain mosquitoes, which, on sucking the blood of an infected vertebrate, take various stages of the parasite into their stomachs with the blood; one stage of the parasite resists the action of the digestive juices of the mosquito and passes through a sexual process of generation and multiplication within the body of the mosquito, the cycle ending after some days with the production of many thousands of minute germs ('photospores,' Ross) lodged in the salivary glands. If the mosquito then succeeds in biting a vertebrate of the right kind, that is to say, of the kind which is a specific host of the parasite in question, the germs pass down its proboscis and are inoculated into the blood, thus bringing about a fresh infection of the disease. Every statement made in the foregoing sentences is based on rigorous experiment or accurate microscopic investigation. It only remains to add that the various species of malarial parasites are specific to certain hosts, vertebrate or insect; those

the Jaroma Company, instance, can be transmitted only by mosquitoes
physicians as a specific for sleeples of men only by the sub-
the reading matter indicated that Jaroma principles of malarial
the same class of humbugs as Oleozone and Plantox of cir-
the efforts of the promoters at that time appeared to be devoted more assiduously to the sale of Jaroma Company stock than to the exploitation of the remedy, it was not considered worth while to make an analysis of the preparation. Recently, however, an advertising campaign for the sale of the remedy has been inaugurated both in the lay and to a limited degree in the medical press. A quarter-page advertisement has been appearing in medical journals often supplemented by a "reader" which still further sets forth the supposed merits of the nostrum. In the advertisements in the daily papers the assertion is made that Jaroma is indorsed by the medical profession and in support of this, parts of the "reading notices" from the medical journals are quoted. Once more then we have the edifying spectacle of medical journals lending their pages to the exploitation of a fraudulent "patent medicine" and aiding and abetting in humbugging the public.

One medical journal which carries advertisements for this nostrum describes Jaroma in part as follows:

> "A DISTINCT ADVANCE IN THE TREATMENT OF INSOMNIA
>
> "Recently a new hypnotic has become available to the profession and careful investigation seems to indicate that an ideal sleep-producer has been discovered. This new product, called Jaroma, is of vegetable origin and is obtained from a gum resin, in turn secured from narthex, a species of umbelliferous plant grown in provinces of Persia and Beloochistan. This gum resin from which Jaroma is prepared has long been used in the Orient for special purpose, while in Great Britain it has been successfully employed medicinally as an antispasmodic.
>
> "Through the use of Jaroma in appropriate dosage, natural sleep is obtained from which in four to eight hours a patient awakens refreshed and vigorous. No after-effect is produced and this eligible remedy is totally devoid of any depressing or toxic action. Its full physiological effect can be obtained as long as necessary without having to increase the dose and it has no habit-forming tendencies."

The circulars accompanying the nostrum are evidently intended for the laity, as may be seen from the following:

> "Are you nervous? Take Jaroma Vegetable Tablets.
>
> "Can't you sleep? Take Jaroma Vegetable Tablets."
>
> "Jaroma Vegetable Tablets, the new & wonderful specific for the 'AMERICAN DISEASE' NERVOUSNESS in its various forms."
>
> " . . . Jaroma is the needed special nerve food to counteract the special strain of modern American business and social life."
>
> "For the discovery of the Jaroma formula we are indebted to an eminent German Nerve Specialist who has had most gratifying results from this compound in his private practice."

Jaroma having gone to the medical profession its examination was taken up by the Association's chemists who reported as follows:

Concerning Sanatorium and Dispensary Treatment of Tuberculosis

To the Editor:—Advocates of sanatorium treatment of tuberculosis have attempted to prove its value by giving the immediate results of treatment. The fact that immediate results are of slight importance in comparison with the ultimate results does not yet seem to be realized. The very name, sanatorium, indicates that it is a place where patients go to be cured, yet few men realize that tuberculosis is not cured in six months, but that it requires three, four or five years. The ultimate results, therefore, in patients who have undergone sanatorium treatment, are really the true test of its value. The economic importance of this question is great, for the cost of maintenance in the sanatorium, while probably less than that in the general hospital, is undoubtedly high. It is impossible to establish sanatoriums in sufficient numbers to accommodate all patients suitable for admission, and further, were this possible, the expense of maintenance would be a grievious tax on the public.

Many attempts have been made to solve this difficult problem of the treatment of tuberculosis among the masses, but not until a few years ago, when special dispensaries for the free treatment of the tuberculous were first established, was any real attempt made to treat tuberculosis outside of the sanatorium. In these dispensaries, not only medical but also material assistance and advice in rega

JAROMA

(Comprising the sedative and hypnotic properties of the gum resin Narthexa and capsicum.)

A remarkably Effective Sleep-Producer, containing *no opiates, chloral, coal-tar or other depressing or habit forming drugs.*

INDICATED IN INSOMNIA
FROM ALL CAUSES

JAROMA produces natural refreshing sleep, lasting several hours from which the patient awakens rested and strengthened with none of the langour or depression common to other hypnotic drugs.

For further information and liberal samples address

JAROMA COMPANY, 89 Fulton St.
New York City

In your reply kindly mention this Publication.

When writing Advertisers, please mention

are troubled with
or sleepless nights the great danger lies in their resorting to remedies that contain *morphine, opiates* or other poisonous and habit forming drugs. These are the remedies physicians were obliged to prescribe before the remarkable *results* obtained from Jaroma, a *purely vegetable* tablet, became known to the *profession.*

The *Medical Council,* one of the leading *medical journals of this country* printed the following in June (1911) under treatment of insomnia:

"TREATMENT OF INSOMNIA

"Insomnia [illegible]

edies have seriously objectionable features, such as tendency to narcotism, depression, secondary stupor, habit forming, etc.

"All this has now been eliminated by a new hypnotic called *Jaroma.* It is of vegetable origin and is obtained from a gum resin secured from an umbelliferous plant grown in Persia, Beloochiston.

"Through the use of Jaroma natural sleep is obtained, from which the patient awakes in four to eight hours refreshed and vigorous. It has no habit-forming tendency, nor is it necessary to increase the dose on prolonged usage. It is free from all opiates or other dangerous drugs."

We advise that you write to the Jaroma Co. of New York for a booklet recently issued upon the subject of insomnia or sleepless nights. It is thoroughly interesting, well illustrated and is sent free upon request. The demand for Jaroma, owing to the public endorsement of the medical press, has naturally become tremendous.

Druggists sell it at 25c and 85c per

Photographic reproduction (reduced about one-half) of typical advertisements of Jaroma. On the left is the advertisement that has appeared in such medical journals as the *International Journal of Surgery, American Medicine, Medical Council, American Journal of Clinical Medicine,* and possibly others; on the right is a typical newspaper advertisement. This particular one appeared in the Buffalo *Evening Times.*

1/10 grain, would have properties similar to Jaroma. As gypsum has been frequently employed as an adulterant of asafetida the analyst has no means of demonstrating whether the calcium sulphate found in the tablets had been added as a "make-weight" or whether it is a part of the "formula" of the "eminent German Nerve Specialist."

he chemists' report this "new vegetable nerve food" is, essentially, asafetida. Although in rational medicine no hypnotic powers are claimed for this drug it is often prescribed in certain forms of hysteria, while as a condiment, it has been known and used from prehistoric times. Therefore, the only new thing about the stuff is its name and the fraudulent use to which asafetida is put. Jaroma is another of those nostrums which are used to humbug both the public and the medical profession.

Miscellany

The Hemoleukocytic Formula in Human Tuberculosis.—The investigation of the changes which the blood undergoes in consumptives has given rise to many studies, and their authors have come to such divergent conclusions that up to the present it has been impossible to establish a well-defined hemoleukocytic formula which might serve as a standard for instituting a more or less exact hematologic diagnosis, as in the case of other diseases. Tuberculosis is a disease which develops between periods of calm and of exacerbations more or less intense, and it is precisely in these intervals that the infection progresses and changes its phases, so that if, in addition to the clinical observation, a repeated examination of the blood is also made, a type of hemoleukocytic desequilibrium may be established which will permit useful deductions to be made respecting the course of the infection, the reactional energy on the part of the organism, the therapeutics and even the provisional prognosis. Following these ideas M. Dominguez (*Sanidad y Beneficencia*, April, 1911) made an attempt to study the question. He has been able to follow thus far the course of forty observations, including adults and children in various stages of the disease. The greatest possible amount of data in relation to the phases of the infection has been obtained, and note of the clinical symptoms has been taken before making the analysis of the blood. In all patients the presence of the Koch bacillus in the sputum was confirmed. The results obtained from the globular count in his cases were as follows: The number of red cells per cubic millimeter oscillated between 2,612,500 (case with hemoptysis, intestinal invasion and bloody diarrhea) and 5,400,000. In only one case of pulmonary and laryngeal tuberculosis, cavitary and with cardiac hypertrophy, did the number reach 7,231,250. The most constant oscillation was between 4.187,000 and 5,921,250. The alterations in the size of the globules were very exceptional; the megalocytes and microcytes occurred only in cases of intense anemia; the achromia and polychromatophilia were slight. The red globules rarely exceeded the normal limits. In tuberculosis the changes in the blood were not constant, but variable from one case to another, and depending on multiple factors differently associated. When there really was anemia, it was moderate. Anemia was rarer and less intense in articular, osseous and vertebral tuberculosis. In exceptional cases, tuberculosis may produce profound anemia and there are two types; anemia at the beginning, frequent not only in the pulmonary but also in the ganglionic form, in which there is a slight hypoglobulia, a marked decrease in hemoglobin and a relative or absolute lymphocytosis. This is the hematologic type of which chlorosis has been made the characteristic and in which many of the so-called chlorotics are only sufferers from anemia due to incipient tuberculosis; the second group includes the anemia of the majority of consumptives who have reached a more or less progressive period of the disease, without hectic fever, and who only present slight alterations of the blood, with an almost normal globular value, and in which the toxemia and cachexia leave no doubt respecting the existence of a globular destruction, which when it does not appear at once, is because it is concealed by an inverse process. Advanced consumptives with hectic fever are generally anemic and the destruction of the blood in these cases is due to septicemia, the disglobulizing process being the same as that of the common septicopyemias. Hyperleukocytosis in consumptives without fever was rarely found, the highest figure being 18,750; in cases of hemoptysis and anemia, hypoleukocytosis more or less pronounced was found. The lowest figure was 3,125; the most frequent variations in different clinical forms oscillated between 6,250 and 12,000. In chronic apyretic tuberculosis or in slightly febrile forms, a polynucleosis of from 66 to 88 per cent., a mononucleosis of from 11 to 15 per cent., and an eosinophilia of from 3 to 10 per cent. were found. In laryngeal tuberculosis, the eosinophilia at times reached 0. In asthmatic consumptives, the figure found was 6.14 per cent. In a child with closed coxalgia and asthma, 8.09 per cent. Lymphocytosis rarely exceeded 46 per cent., the large and medium-sized cells predominating. Persistent lymphocytosis in closed coxalgias was notable, the figure varying between 31 and 40 per cent. Large mononuclears varied between .62 and 15.67 per cent., the most constant figures being from 9 to 12 per cent. In a general way, therefore, Dominguez finds that unadvanced consumptives with small hemorrhages, with fever and scant expectoration and tendencies to regression, present a leukocytosis of 9,000 to 12,500, a low mononucleosis of 12 to 15 per cent., and an eosinophilia which at times reaches over 5 per cent. when the manifestations cease and which maintains itself more or less in relation to the period of apparent recovery. In the laryngeal forms there is a lymphocytosis of between 25 and 35 per cent. In tuberculous coxalgias in children, there is a slight or no hypoleukocytosis, 37 to 55 per cent. polynuclears, and 4 to 8 per cent. polynuclear eosinophilia, the characteristic of these forms being the lymphocytosis, at times reaching 46 per cent.

Prophylaxis of Epidemic Poliomyelitis in Norway.—The authorities in Norway published in June an appeal to physicians to be on the lookout for acute poliomyelitis, saying that it has recently appeared at different points throughout the country and the number of cases and the virulence of the disease as observed now surpass all experiences since the epidemics of 1905. After referring to the circular, issued by the authorities in 1904, the appeal calls attention further to the necessity for isolation of the sick and their attendants during the acute stage (as a rule, for three weeks after the first symptoms). Especial care must be taken to sterilize the secretions from the nose and throat, and the dishes and spoons, etc., used by the sick must be boiled at once. All who have been in recent contact with the sick should be advised to gargle frequently with solutions of potassium permanganate or hydrogen dioxid, and the sick should do this also to render their secretions harmless for others. A terminal disinfection of the room is necessary as for other infectious diseases. Although there is no certain evidence of transmission of the disease by foodstuffs, yet this possibility should not be disregarded, as also the possibility of healthy carriers. The frequency of sore throat as an early symptom of poliomyelitis should be borne in mind, and persons with sore throat who have been exposed to poliomyelitis should be regarded as suspects. Mild abortive cases of poliomyelitis play an important part in the spread of the disease. Physicians are requested to notify the authorities of every new case, with a detailed case-history and remarks on the etiology which the case may suggest, and they are also asked to report the ultimate outcome. The appeal is published in detail in the *Tidsskrift for den Norske Lægeforening*, July 1, 1911, page 92.

Columbia University Quarterly.—This interesting publication often takes up matters of wide general interest. A recent number has several articles of general interest in the educational world, some pictures pertaining to the university and excellent pictures of two physicians who have recently died, Drs. Hermann Knapp and Edward G. Janeway. In a brief sketch of the career of Edward G. Janeway, Dr. Horst Oertel especially points to the eminence of Janeway's lifework as a pioneer in the development of scientific medicine in this country. His position in the field of pathologic anatomy is compared with the work Virchow was doing contemporaneously in Europe; both men breaking with the old scholasticism in the conception of disease. Oertel says that to Janeway a disease was never a type or a collective name given to pigeonholed association of fossilized ideas, but a living localized anatomic process for whose proper understanding one had to reconstruct former experiences. He approached his cases, therefore, with the attitude of the natural scientist. Among his achievements are mentioned that he was the first in this country to champion the infectious nature of tuberculosis; that he gave a description of leukemia for the first time in America, based on his own observations; and that to him we owe the first comprehensive, systematic presentation of syphilitic fever made anywhere. His activity in the establishment of pathologic anatomy as the objective basis of all rational medical thought and practice, may, however, be regarded as his greatest contribution to medicine.

The Malarial Cycle.—Reviewing Professor Ross' "Prevention of Malaria," E. A. Minchin says in *Science Progress* that "the malarial theorem, as Ross aptly terms it, may be stated briefly as follows: Malaria in man or animals is a disease caused by a minute parasite which lives and multiplies in the blood, passing its trophic phase within the red blood-corpuscles. The parasite is propagated from one vertebrate host to another by the agency of certain mosquitoes, which, on sucking the blood of an infected vertebrate, take various stages of the parasite into their stomachs with the blood; one stage of the parasite resists the action of the digestive juices of the mosquito and passes through a sexual process of generation and multiplication within the body of the mosquito, the cycle ending after some days with the production of many thousands of minute germs ('photospores,' Ross) lodged in the salivary glands. If the mosquito then succeeds in biting a vertebrate of the right kind, that is to say, of the kind which is a specific host of the parasite in question, the germs pass down its proboscis and are inoculated into the blood, thus bringing about a fresh infection of the disease. Every statement made in the foregoing sentences is based on rigorous experiment or accurate microscopic investigation. It only remains to add that the various species of malarial parasites are specific to certain hosts, vertebrate or insect; those of birds, for instance, can be transmitted only by mosquitoes of the subfamily Culicinæ; those of men only by the subfamily Anophelinæ." The aims of the principles of malarial prevention must be to interrupt the complex chain of circumstances on which the existence of the parasite depends. If the parasite cannot pass from man into the mosquito, or from the mosquito into man, it becomes extinct with the death of its host, if not before, says Professor Ross, and he offers three general principles of prevention: (1) mosquito reduction; (2) treatment of human beings with quinin; (3) protection of human beings against mosquitoes. Of these three principles—of which neither can be carried out completely—he regards the first-named (mosquito reduction) as giving the best results.

The Investigator's Curiosity.—As children we all have an instinctive curiosity concerning the world about us, a curiosity which most of us gradually lose as we fit ourselves into the social conventions. The investigator is one, however, in whom his natural curiosity still persists. He has never got past the annoying stage of asking "Why?" The events occurring on every side which are matters of course to most men, startle him into wonderment. Why does the spinning top not fall? Why do animals breathe faster when they run? Why does disturbed water take the form of waves? Why do roots grow downward? Why does the mouth become dry when one speaks in public? Such are the questions that arise. The answers to them may be incalculably valuable to mankind. The microscope revealed to Pasteur strange organisms in bad tasting wines. Why may not the disease of the wine, he asked himself, be due to the growth of these unusual germs within it? And later when he found germs also in silkworms, the further question was suggested: Why may not animals likewise become diseased in exactly the same manner? Whether the surmises of the investigator are true, the testimony of other men usually does not tell. He must turn to Nature herself and put the idea to the test of observation and experiment.—Cannon in *Science*.

Woman's Vital Resistance.—Woman excretes less carbonic acid and therefore is in less need of oxygen and needs it less vitally than man. This is thought to be a factor in woman's greater capacity to endure heat, especially the heat of rooms of high temperature, as is seen in bakeries and in the manufacture of charcoal, where it is said that women are little inconvenienced by a very high temperature. This is thought, also, one of the reasons why women experience less discomfort than men in breathing the rarefied air of high altitudes, and why, too, that women suffer less from chloroform anesthetics; and, for want of a better explanation, it has been given as the reason why women criminals more often survive hanging than men.—Stewart in the *Medical Record*.

Concerning Sanatorium and Dispensary Treatment of Tuberculosis

To the Editor:—Advocates of sanatorium treatment of tuberculosis have attempted to prove its value by giving the immediate results of treatment. The fact that immediate results are of slight importance in comparison with the ultimate results does not yet seem to be realized. The very name, sanatorium, indicates that it is a place where patients go to be cured, yet few men realize that tuberculosis is not cured in six months, but that it requires three, four or five years. The ultimate results, therefore, in patients who have undergone sanatorium treatment, are really the true test of its value. The economic importance of this question is great, for the cost of maintenance in the sanatorium, while probably less than that in the general hospital, is undoubtedly high. It is impossible to establish sanatoriums in sufficient numbers to accommodate all patients suitable for admission, and further, were this possible, the expense of maintenance would be a grievous tax on the public.

Many attempts have been made to solve this difficult problem of the treatment of tuberculosis among the masses, but not until a few years ago, when special dispensaries for the free treatment of the tuberculous were first established, was any real attempt made to treat tuberculosis outside of the sanatorium. In these dispensaries, not only medical advice but also material assistance and advice in regard to many questions pertaining to the home have been given freely. While the object of these dispensaries was at first to treat the tuberculous, it is now recognized that their main object is to prevent tuberculosis in the communities in which they are situated. However, for a time, the dispensary, in which many more patients could be treated than could ever be admitted to the sanatoriums, was looked on as vastly more important in the treatment of tuberculosis among the poor than the sanatorium. Many reasons were advanced to uphold this view. When a patient applied to the dispensary for treatment, the other members of his family were subjected to examination. Many early cases of tuberculosis were thus discovered and the problem arose at once as to what steps should be taken. In a large majority of instances, these patients could not afford to give up work, or leave home, and the question at once arose as to the efficacy of the dispensary treatment of tuberculosis.

A large number of individuals among the families of the tuberculous poor who apply for treatment at the dispensary, are found to show physical signs in the lungs. Some of them have symptoms and should be treated. Others have no symptoms and there is grave doubt as to whether these patients need anything more than careful watching. There can be no doubt that some of the good results obtained in dispensary or sanatorium treatment are due to the fact that such individuals have been subjected to treatment. It certainly seems unnecessary to treat patients for a disease of which they present no symptoms. They do, however, need careful watching and here the dispensary may do work of inestimable value. A number of dispensaries in America have published reports of the immediate results of treatment but such figures carry far less weight than the percentages of living, dead and untraced among a number of carefully classified patients. There is no doubt great difficulty in following these patients either to their death or to recovery at the end of five years, but with the excellent facilities at the disposal of many modern dispensaries, such, for example, as the visiting nurses, the various relief associations and the hearty cooperation of the boards of health, such work should present no insurmountable difficulties.

As yet, few, if any, carefully worked out statistics from dispensaries, showing the ultimate value of dispensary treatment, have been published. This method need not necessarily be pursued by every dispensary, but a number of dispensaries in, for instance, Baltimore, Boston, Chicago, New York and Philadelphia, could undertake this work for a series of years. There is no doubt that the class system introduced by Pratt adds the breath of life to many dispensaries. It will be of great value to compare results obtained in the dispensaries before and after the introduction of this method. Many patients from the dispensaries are sent to sanatoriums; on return they should report to the dispensary. These patients should be studied separately and the problem of the best treatment of tuberculosis might then be solved.

There are few figures with which to compare the ultimate results obtained in sanatoriums. In a recent letter to the Lancet (1910, ii, 1446), Davies compares the results in 278 patients who did not go to a sanatorium with fifty who did. Excluding eighty-eight who died within three months, he was able to trace 116 patients, of whom 100 had died at the end of four years, and apportioning the seventy-four untraced patients in a similar manner, 14 per cent. of them were estimated to be alive, while 50 per cent. of the sanatorium-treated patients were living.

Many of the first class might not have been accepted in a sanatorium; still the very great difference (an increase of 250 per cent.) is very suggestive. Careful classification by dispensary physicians could render their figures exactly comparable in the two classes.

When seeking to compare the ultimate results of sanatorium treatment with other figures, Elderton and Perry ("A Third Study of the Statistics of Pulmonary Tuberculosis: The Mortality of the Tuberculosis and Sanatorium Treatment," Dulau & Co., London, 1910), on account of the paucity of more recent statistics were forced to refer to Williams' 1,000 cases reported among the well-to-do in 1872, and to the figures obtained from Pollock's "Elements of Prognosis," published in 1865. The results of this study show that whereas the death-rate in the sanatorium patients is about fourteen or fifteen times the ordinary death-rate, the patients treated by Williams and by Pollock had a death-rate only two or three times the ordinary.

The question is an important one. The sanatorium workers cannot solve it alone and must turn to others for aid. The organization of many dispensaries is at present so perfected that such work as we have outlined, while laborious, should be easy of accomplishment.

Alopecia—Baldness

To the Editor:—An article on this subject in The Journal (Aug. 12, 1911) gives the causes of this very common and annoying trouble. As personal experience counts for much, I will give the treatment which in my own case has up to 70 years of age preserved a full and even growth of hair over the entire head, with no "skating rink" visible, or even thinness of hairy covering on the vault of the cranium. By inheritance I should have been bald at 45 or 50 years, as all my near relatives have shown that peculiarity; in fact, I know of none of the male members of my family as far removed as cousins who was not more or less deficient in hirsute covering of the head.

At about 40 years of age I began to notice that my hair was becoming somewhat dry and lifeless, and did really begin to drop out in rather alarming amount, so that I set about trying some means to prevent it. A friend advised me to get a wire brush, which I immediately did, and every morning I dampened (not soaked) the entire scalp with cold or lukewarm water. I used a comb only in the parting of the hair, the wire brush did the rest. About once a week I have used a little oil or grease, having tried several kinds; the most satisfactory effect was produced by cocoanut-oil. It keeps the hair soft and silky and does not mat the hair or plaster it down. Usually about once a month, when at the barber for a hair-cut (a trim, not a shingle) I get a good shampoo; I think that is often enough for a thorough scrubbing.

The wire brush keeps the scalp pretty free from dirt and dandruff, in fact I think the brush is the main factor in the treatment. By its gentle and not disagreeable friction of the scalp, it promotes the circulation and thus brings nourishment to the hair-bulbs, and gives vigor to the growing hair.

S. Hendrickson, M.D., Brooklyn.

Certified Butter in California

To the Editor:—I have read with interest the article by Dr. Hess on "The Need for a Certified or Pasteurized Butter," in The Journal, August 12, 1911.

It may be of interest to your readers to know that the California State Association of Medical Milk Commissions, April 19, 1911, adopted a full set of rules for the production of "certified butter," in accordance with a recent act of the legislature delegating the certification of butter to medical milk commissions. At a milk conference held in July, 1911, at the University of California, there was exhibited "guaranteed butter," labeled, "This butter is made from efficiently pasteurized cream. Guaranteed by the Regents of the University of California under the Food and Drugs Act, June 30, 1906, Serial No. 38,491." The experimental work leading to the adoption of both these measures is reviewed in The Journal, March 18, 1911, under the title, "Certified Butter in California." This communication states that the certification was to be on a basis of pasteurization. In conference, however, the milk commissions of the state decided that a pasteurized butter could not qualify as "certified."

Excision as a Method of Treating Spider Bites

To the Editor:—The treatment of spider bites with medicine has proved so extremely unsatisfactory in my experience that I have tried excising a small piece of tissue in three cases during this year and in all cases the results have proved satisfactory. Reasoning that the tissue would slough and that excising is the best treatment in carbuncle or in any condition of sloughing, I thought that excision would prove best in cases of spider bites and so it has. The part can be rendered painless by injecting 1/10 of 1 per cent. solution of cocain or some local anesthetic and if this is done properly the wound gets well rapidly. The low resistance of fat makes it necessary to excise a larger piece than one would at first think necessary. It is best to go to the underlying muscle or else sloughing may occur at the bottom of the wound. The amount of tissue necessary to be excised depends on conditions present, the length of time after the bite, and so forth. As a rule the pain stops and the patient is comfortable after the operation.

John W. Matlock, Frost, Tex.

Royal Order of Lions Fraud

To the Editor:—I saw the statement of Dr. Charles F. Brigham in The Journal, August 26, regarding the "Royal Order of Lions" fraud. The promoter of this concern was in our town May 15, and showed me the receipts of half a dozen physicians of surrounding towns who had signed his contract. After discussing the matter with my father, who was present, and to whom the contract also seemed good, I "bit."

I received a bunch of blanks and other printed matter setting forth the benefits to be derived from a membership in the order, etc., with the stamped address 209½ Brady St. (Phone N. 4402-L), supposedly Decatur, Ill. I sent a letter to Decatur which was forwarded to Madison, Wis., and from there to Green Bay, Wis., and then returned unclaimed.

Louis H. Miller, M.D., Pana, Ill.

Southerners Being Separated from Their Money

To the Editor:—There is a sharper who has been working the physicians here in the south. He pretends to be an old graduate and usually states that he wants a draft endorsed so that he may obtain money to pay the burial expenses for some of his relatives, or to have a relative operated on. He is about 5 feet 10 inches in height and of a swarthy complexion. If you will call attention to this in The Journal and ask anyone that he tries to bunco to have him arrested and wire the chief of detectives in Nashville you will be conferring a great favor.

Lucius E. Burch, Nashville, Tenn.

Chalk Paste Not a Good Substitute for Bismuth Paste

To the Editor:—In THE JOURNAL, July 29, Dr. James R. Mitchell advocates the use of chalk paste as a substitute for Beck's bismuth paste. Though my experience with bismuth paste has been slight, and with chalk paste none at all, still I would caution against the substitution of the latter for the former. Whoever has had experience with bismuth subnitrate and calcium carbonate in various inflammatory conditions, knows that chalk cannot do what bismuth salts can do. In subacute or chronic gonorrhea, in simple diarrhea, in cholera infantum or cholera morbus, in various dermatologic conditions we cannot substitute chalk for bismuth, for bismuth possesses siccative, granulation-promoting and astringent properties which chalk does not possess. That it is not the nitrate radical that is responsible for these desirable properties is evident from the fact that the same properties are possessed by other bismuth combinations, such as the subcarbonate, the oxid, the hydrate (milk of bismuth), the salicylate, etc. The statement, therefore, that the bismuth in the bismuth paste acts merely as a mechanical stimulant seems to me unwarranted, and the caution against the substitution recommended by Dr. Mitchell is, in my opinion, a very necessary one.

WILLIAM J. ROBINSON, M.D., New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter *must contain the writer's name and address, but these will be omitted, on request.*

OPERATION ON AN ANKYLOSED KNEE

To the Editor:—Can you give me any information regarding the operation on an ankylosed knee by which some function is restored to the joint? JOHN J. MCKENNA, Philadelphia.

ANSWER.—It is assumed that the term "ankylosed knee" in the above question refers to one in which true synostosis has taken place. The principle underlying the successful treatment of synostosed joints consists in the interposition, between the separated ends of the bones forming the joint, of some non-absorbable material which will prevent the bones from reuniting. The knowledge that the accidental interposition of fascia or other soft tissue between the fractured ends of a long bone frequently leads to non-union with the formation of a false joint, is undoubtedly what gave rise to the idea of interposing similar material between the ends of the bones to prevent the reunion of the bones in the ankylosed joint. The materials which have been introduced for this purpose are numerous, and are both *inorganic and organic*. The introduction of inorganic materials, such as Payr's magnesium plates, etc., has not been followed by very encouraging results. The use of organic material, on the other hand, has been followed by much *more favorable results*. Organic material may be used in the shape of dead membrane, such as hog's bladder acted on by chromic acid, or it may be used in the shape of living tissue consisting of transplanted flaps taken from the same individual. The latter *method* is the *one* which has given the best results. The tissue in the latter method may consist of entirely detached flaps of periosteum, or of attached flaps consisting of the fascia lata, together with subcutaneous fat.

If periosteal flaps are used the knee-joint is opened by a suitable incision which freely exposes the entire joint; the synostosed bones are separated with a chisel, the raw bony surfaces made as smooth as possible, that *on the tibia being* made slightly concave and that on the femur slightly convex, so that the one will fit the other approximately in the normal manner. An incision is then made over the inner surface of the tibia, usually at the upper part. A flap of periosteum is raised from the bone so as to include its osteogenetic layer. This detached periosteal flap, which should be large enough to cover the denuded surfaces of the bone, is then transferred to its proper surface, where it is stitched with catgut to hold it in place. A similar periosteal flap is then applied to the denuded surface of the other bone in the same manner. If motion of the joint is limited by cicatricial or contracted ligaments or bands, these are removed. The joint is then closed by properly suturing the soft parts around it. the operation wound over the tibia is likewise closed, and the leg is placed in a plaster cast.

In using attached flaps there may be used a single unilateral flap consisting of the fascia lata and fat covering it, which may be dissected up and turned into the joint, or bilateral flaps may be made. The latter is preferable, as the single long flap is more likely to undergo destructive absorption than two shorter bilateral flaps. The bones, of course, are prepared as already mentioned, and the flaps are sutured in place, the joint closed and the leg placed in a plaster cast. In order to be successful, this operation requires a high degree of technical skill, much experience and good judgment in the selection of proper cases for the operation.

WHAT IS THE "LAST ILLNESS"?

To the Editor:—There is a statute in my state which gives priority in favor of the claims of physicians for services rendered during the last illness of a decedent to an amount not exceeding $50. Please inform me what is meant by the phrase "services rendered during the last illness of the decedent." Would it cover any fixed period of time, for example, if a man suffered from consumption or Bright's disease for one or more years and then died of pneumonia or uremia? D. P. C., Va.

ANSWER.—A "last illness," under such a statute, according to Pennsylvania decisions cited in "Five Words and Phrases Judicially Defined," 4007, means the immediate illness resulting *in the decedent's death. It does not include the illness* caused by a serious injury from which he so far recovers that he is able to attend to business, but has a subsequent relapse. Nor can it be construed to include a lingering illness that has stretched across *many months or many years*. Men sometimes die from diseases of the heart, lungs or other organs, which commence with infancy, terminating only with old age. They are never well, always complaining, but lingering on throughout the usual period allowed to human life. In other instances the disease runs its course in a shorter time, but still the patient lingers, down at times, up and about at others. Such cases, where the illness is so protracted, the statute certainly does not contemplate. Where the disease assumes a fatal form, runs its course rapidly, the patient virtually prostrated, and the services of a physician constantly necessary, the case just as certainly is contemplated. Where a person suffered from softening of the brain, the progress of the disease being gradual and slow, the patient living for more than a year after the physician's *attendance* commenced, going about the house, waiting on herself generally, once visiting abroad for several weeks, the disease manifesting itself only in weakness and irritability up to within a short time of her death, when it resulted in apoplexy, prior to which the physician's attendance was irregular, he going only when called, but subsequent to the apoplexy his visits were regular and pretty constant, the latter period was the "last illness" for the services during which the physician was entitled to preference.

The term "last illness," however, has been held to include medical services rendered to a patient for a year and a half prior to his death, where he was suffering during the period from an incurable, progressive disease which resulted in his death.

TRICHOMONAS INTESTINALIS

To the Editor:—Please tell me whether or not *Trichomonas intestinalis* has any pathologic possibilities. I have a patient whose blood shows a most profound anemia with an increase in the eosinophils; white count normal. Repeated examinations of the stool show large numbers of the *Trichomonas intestinalis*. Is there any recent literature relative to this?

N. R. HARLAN, Freeport, Ill.

ANSWER.—*Trichomonas intestinalis* is commonly found in the intestinal canal, especially in cases of diarrhea. Hence the organisms are often seen in stools in cases of typhoid fever, cholera, chronic enteritis, etc. They are also not infrequently found in normal stools. Because they are so sensitive to acid, they do not ordinarily occur in the stomach but in conditions of diminished acidity, as for example, carcinoma, they may be found there in large numbers. Thus, their presence may be of some significance for diagnosis. Their pathogenic possibilities seem to be limited to sustaining or aggravating already existing catarrhal conditions, though some difference of opinion seems to exist regarding this point. Cases of severe chronic enteritis have been reported for which no cause could be found other than the large number of these parasites *constantly found* in the stools. For example, Askanazy (Aschoff's "Pathologische Anatomie," 1909, *i*, *183*), mentions such a case which resulted fatally and in which autopsy revealed no other cause for the intense chronic *ulcerative* adds the breath of life to many dispensaries. It will be of great value to compare results obtained in the dispensaries before and after the introduction of this method. Many patients from the dispensaries are sent to sanatoriums; on return they should report to the dispensary. These patients should be studied separately and the problem of the best treatment of tuberculosis might then be solved.

There are few figures with which to compare the ultimate results obtained in sanatoriums. In a recent letter to the Lancet (1910, ii, 1446), Davies compares the results in 278 patients who did not go to a sanatorium with fifty who did. Excluding eighty-eight who died within three months, he was able to trace 116 patients, of whom 100 had died at the end of four years, and apportioning the seventy-four untraced patients in a similar manner, 14 per cent. of them were estimated to be alive, while 50 per cent. of the sanatorium-treated patients were living.

Many of the first class might not have been accepted in a sanatorium; still the very great difference (an increase of 250 per cent.) is very suggestive. Careful classification by dispensary physicians could render their figures exactly comparable in the two classes.

When seeking to compare the ultimate results of sanatorium treatment with other figures, Elderton and Perry ("A Third Study of the Statistics of Pulmonary Tuberculosis: The Mortality of the Tuberculosis and Sanatorium Treatment," Dulau & Co., London, 1910), on account of the paucity of more recent statistics were forced to refer to Williams' 1,000 cases reported among the well-to-do in 1872, and to the figures obtained from Pollock's "Elements of Prognosis," published in 1865. The results of this study show that whereas the death-rate in the sanatorium patients is about fourteen or fifteen times the ordinary death-rate, the patients treated by Williams and by Pollock had a death-rate only two or three times the ordinary.

The question is an important one. The sanatorium workers cannot solve it alone and must turn to others for aid. The organization of many dispensaries is at present so perfected that such work as we have outlined, while laborious, should be easy of accomplishment.

Lawrason Brown, Saranac Lake, N. Y.

Alopecia—Baldness

To the Editor:—An article on this subject in The Journal (Aug. 12, 1911) gives the causes of this very common and annoying trouble. As personal experience counts for much, I will give the treatment which in my own case has up to 70 years of age preserved a full and even growth of hair over the entire head, with no "skating rink" visible, or even thinness of hairy covering on the vault of the cranium. By inheritance I should have been bald at 45 or 50 years, as all my near relatives have shown that peculiarity; in fact, I know of none of the male members of my family as far removed as cousins who was not more or less deficient in hirsute covering of the head.

At about 40 years of age I began to notice that my hair was becoming somewhat dry and lifeless, and did really begin to drop out in rather alarming amount, so that I set about trying some means to prevent it. A friend advised me to get a wire brush, which I immediately did, and every morning I dampened (not soaked) the entire scalp with cold or lukewarm water. I used a comb only in the parting of the hair, the wire brush did the rest. About once a week I have used a little oil or grease, having tried several kinds; the most satisfactory effect was produced by cocoanut-oil. It keeps the hair soft and silky and does not mat the hair or plaster it down. Usually about once a month, when at the barber for a hair-cut (a trim, not a shingle) I get a good shampoo; I think that is often enough for a thorough scrubbing.

The wire brush keeps the scalp pretty free from dirt and dandruff, in fact I think the brush is the main factor in the treatment. By its gentle and not disagreeable friction of the scalp, it promotes the circulation and thus brings nourishment to the hair-bulbs, and gives vigor to the growing hair.

S. Hendrickson, M.D., Brooklyn.

Certified Butter in California

To the Editor:—I have read with interest the article by Dr. Hess on "The Need for a Certified or Pasteurized Butter," in The Journal, August 12, 1911.

It may be of interest to your readers to know that the California State Association of Medical Milk Commissions, April 19, 1911, adopted a full set of rules for the production of "certified butter," in accordance with a recent act of the legislature delegating the certification of butter to medical milk commissions. At a milk conference held in July, 1911, at the University of California, there was exhibited "guaranteed butter," labeled, "This butter is made from efficiently pasteurized cream. Guaranteed by the Regents of the University of California under the Food and Drugs Act, June 30, 1906, Serial No. 38,491." The experimental work leading to the adoption of both these measures is reviewed in The Journal, March 18, 1911, under the title, "Certified Butter in California." This communication states that the certification was to be on a basis of pasteurization. In conference, however, the milk commissions of the state decided that a pasteurized butter could not qualify as "certified."

Southerners Being Separated from Their Money

To the Editor:—There is a sharper who has been working the physicians here in the south. He pretends to be an old graduate and usually states that he wants a draft endorsed so that he may obtain money to pay the burial expenses for some of his relatives, or to have a relative operated on. He is about 5 feet 10 inches in height and of a swarthy complexion. If you will call attention to this in The Journal and ask anyone that he tries to bunco to have him arrested and wire the chief of detectives in Nashville you will be conferring a great favor.

Lucius E. Burch, Nashville, Tenn.

enteritis found. He states further that these parasites seem to be able to cause diarrhea in children. There seems to be no evidence that they may directly cause anemia.

References in the literature to the pathogenesis of *Trichomonas intestinalis* are not numerous. Hare's "Practice of Medicine," 1907 edition, says that it is not important from a clinical point of view. Anders' "Practice," 1909 edition, says that the organism is not important from a pathogenic standpoint. Ricketts and Dick, in the last edition (just issued) of "Infection. Immunity and Serum Therapy," 1911, say: "It seems to be of not much pathogenic significance but finds in the liquid stools and in alkaline reaction conditions which favor its proliferation. It may be transmitted as a contagion." This book gives Epstein as the authority for the latter statement. An article in THE JOURNAL, Oct. 15, 1910, p. 1377, by G. C. Dalley, assigns *Trichomonas intestinalis* as the only discoverable cause of a case of gangrene of the lung.

DOSAGE OF SODIUM BICARBONATE

To the Editor:—Hale found that caffein was useless and sometimes even harmful when given with acetanilid to antagonize its harmful effects, but that sodium bicarbonate lessens the toxicity of acetanilid. However, I have seen no mention of the amount or the dose that was best given for this purpose as determined by experimentation. Can you give me any light on this?

C. E. MCREYNOLDS, M.D., Goodrich, N. D.

ANSWER.—On writing to Dr. Hale, we learn that he is not able to answer definitely the questions concerning the relative doses of acetanilid and sodium bicarbonate, but that he believes, from his experimental work, that fairly large doses of the bicarbonate are indicated. He suggests at least 3 grains to every 2 of acetanilid. In case of poisoning he suggests giving as an antidote sodium bicarbonate in divided doses up to 15 or 30 grains, depending on the effect produced. He states that so far as he knows, his laboratory findings have not been put to test by clinical trial.

THE NOGUCHI AND MUELLER MODIFICATIONS OF THE WASSERMANN TEST

To the Editor:—What is the present status of the Noguchi modification of the Wassermann reaction? Is it considered as reliable as the Mueller modification? Can you give the Mueller technic or tell where it may be secured?

L. O. T.

ANSWER.—In the opinion of European authorities and some American, the Noguchi test is not so reliable as the original Wassermann. Many Wassermann workers regard it as not to be depended on alone. The Mueller modification is much more reliable. Its chief difference from the original Wassermann lies in the use of smaller amounts of the various reagents—a drop method. A consideration of the Mueller method will be found in the *Wiener klinische Wochenschrift*, 1907, No. 17, p. 514; 1908, No. 9, p. 282; 1909, No. 40, p. 1376.

The Public Service

Medical Department, U. S. Army

Changes during the week ended Aug. 26, 1911.

Van Poole, G. M., major, detailed to represent the Medical Department of the Army at meeting Association Military Surgeons of U. S., Milwaukee, Wis., September 26 to 30.

Clayton, George R., M.R.C., granted two months' and ten days' leave of absence.

Wilson, William H., major, granted fifteen days' leave of absence.

Brewer, Isaac W., M. nted one month and fifteen days'
leave of absence.
Richard, Charles, col thirty days' leave of absence.
Snyler, Henry D., lie o represent the Medical
Department of the Arm the American Hospital
Association to be held i 19 to 21.
Smith, Herbert H., M leave of absence.
Patterson, Edwin W., his present leave
of absence ordered to U duty.
Appel, Daniel col ded one month.
Stone, Fran io of Monterey,
Cal., *from* ter San Francisco.
Eastman, s attending
suurgeon, N , *for duty*.
Peed, Ge sence.
Ford, Jo s No.

General
Ashburn,
De
the
dqu
ding

Cutliffe, William O., M.R.C., is relieved from duty at Fort McIntosh, Texas, and will proceed to Fort Lawton, Wash., for duty as surgeon on transport *Dix*.

Bushnell, George E., colonel, is detailed to represent the Medical Department of the Army at annual meeting of New Mexico Tuberculosis Society at Las Vegas, September 6 to 9.

Lambie, John S., Jr., captain, on expiration of leave, will proceed to Fort McHenry, Md.

Robbins, Chandler P., major, is relieved from duty at Fort McHenry, Md., and will proceed to Fort Sill, Okla., for duty.

Duval, Douglas F., major, when relieved from duty at Fort Sill, will proceed to Fort Benjamin Harrison, Ind., for duty.

Suggs, Frank, M.R.C., having reported at Seattle, Wash., will proceed to Fort Lawton, Wash., for temporary duty.

Birmingham, Henry P., colonel, reports his departure, August 8, for Washington, D. C.

Casper, Joseph, first lieut., August 22, reports return from leave to sick in quarters this date, Fort Du Pont, Del.

Suggs, Frank, M.R.C., August 3, reports departure from Fort Egbert, Alaska, for Seattle, Wash.

Cooper, Wibb E., first lieut., August 5, reports departure for Manila on transport *Sheridan*.

Ferenbaugh, Thomas S., first lieut., August 16, reports departure from Langtry, Texas, for Barksdale, Texas, August 18, reports his arrival at Barksdale, Texas.

Gentry, Ernest A., first lieut., August 16, reports departure from Langtry, Texas, for Barksdale, Texas, August 18, reports arrival at Barksdale.

Usher, F. M. C., major, August 21, reports arrival at Fort Sam Houston, Texas, from Camp Mabry, Austin (Maneuvers Texas National Guard).

Pyles, W. L., captain, August 22, reports arrival at Fort D. A. Russell, Wyo.

Hall, J. F., captain, August 23, reports arrival at Fort Strong, Mass., for duty.

Denton, William, first lieut., August 21, reports arrival at Fort Sam Houston, from Camp Mabry, Austin, Texas (Maneuvers Texas National Guard). August 22, reports departure from Fort Sam Houston for temporary duty at Fort Bliss.

De Laney, Matthew A., major, granted leave of absence for one month to take effect about Aug. 24, 1911.

Medical Corps, U. S. Navy

Changes for the week ended Aug. 19, 1911.

Gatewood, J. D., medical director, commissioned medical director from July 11, 1911.

Gates, M. F., medical inspector, commissioned a medical inspector from July 11, 1911.

Shepard, G. W., P. A. surgeon, commissioned P. A. surgeon from Oct. 25, 1910.

Chambers, W., P. A. surgeon, commissioned P. A. surgeon from March 19, 1911.

Bacon, S., Melhorn, K. C., and McGuire, L. W., P. A. surgeons, commissioned P. A. surgeons *from* April 11, 1911.

Boland, M., P. A. surgeon, commissioned P. A. surgeon from July 12, 1911.

Phelps, J. R., and Clifton, A. L., P. A. surgeons, commissioned P. A. surgeons from July 15, 1911.

Henry, R. B., asst.-surg., detached from U. S. S. *Rainbow* and ordered to the naval hospital, Canacao, P. I.

Pratt, L. L., asst.-surg., detached from the naval hospital, Canacao, P. I., and ordered to the U. S. S. *Rainbow*.

Changes for the week ended Aug. 26, 1911.

Hoyt, R. E., surgeon, commissioned surgeon from June 11, 1911.

Jones, R. F., asst.-surgeon, commissioned assistant surgeon from Aug. 2, 1911.

Thomas, G. C., P. A. surgeon, detached from the navy recruiting station, Philadelphia, and ordered to the *Rhode Island*.

Schier, A. R., acting asst.-surgeon, appointed acting assistant surgeon from Aug. 16, 1911.

Donelson, M., P. A. surgeon, detached from the naval hospital, Newport, R. I., and ordered to the *Glacier*.

Dykes, J. R., P. A. surgeon, detached from the navy-yard, Portsmouth, N. H., and ordered to the naval hospital, Mare Island, Cal., for duty.

Diehl, O., medical director, commissioned medical director from July 20, 1911.

Lownes, C. H. T., medical inspector, commissioned medical inspector from July 20, 1911.

Evans, S. G., surgeon, detached from the *Pennsylvania* and ordered home to wait orders.

Bachus, J. W., P. A. surgeon, detached from the *Iris* and ordered to the *Pennsylvania*.

Owens, W. D., P. A. surgeon, ordered to duty at the naval hospital, Newport, R. I.

Giltner, H. A., asst.-surgeon, detached from the *Glacier* and ordered to the *Iris*.

U. S. Public Health and Marine-Hospital Service

Changes for the week ended Aug. 16, 1911.

Pettus, W. J., assistant surgeon-general, granted twelve days' leave of absence from Aug. 15, 1911.

Irwin, Fairfax, surgeon, granted nineteen days' leave of absence from June 27, 1911, on account of sickness.

Magruder, G. M., surgeon, granted seventeen days' leave of absence from Aug. 13, 1911.

Geddings, H. D., surgeon, leave of absence for one month from June 23, 1911, on account of sickness, amended to read twenty-one days.

Nydegger, J. A., surgeon, granted two months' leave of absence from July 24, 1911.

Francis, Edward, P. A. surgeon, granted one day's leave of absence July 31, 1911; granted seven days' leave of absence from Aug. 1911, under paragraph 191, Service Regulations.

Ebersole, R. E., P. A. surgeon, granted eight days' leave of absence from Aug. 5, 1911, under paragraph 191, Service Regulations.

Pettyjohn, Jos., P. A. surgeon, granted one month's leave of absence from Aug. 16, 1911.

Ashford, F. A., P. A. surgeon, granted one month's leave of absence from Aug. 17, 1911.

Preble, Paul, asst.-surg., granted one month's leave of absence from Aug. 14, 1911.

Grimm, R. M., asst.-surg., directed to proceed to Pineville, Ky., via Columbia, S. C., on special temporary duty.

Kolb, L., asst.-surg., granted seven days' leave of absence from Aug. 11, 1911, under paragraph 191, Service Regulations.

Boyd, Frank, A. A. surgeon, granted twenty-six days' leave of absence from Aug. 6, 1911.

Watson, Harry J., A. A. surgeon, leave of absence for thirty days from Aug. 14, 1911, amended to read thirty days from Aug. 2, 1911.

Wilbert, Martin I., technical assistant, detailed to represent the Service at the meeting of the American Pharmaceutical Association to be held at Boston Aug. 14 to 19, 1911.

Medical Economics

This Department Embodies the Subjects of Post-graduate Work, Contract Practice, Legislation, Medical Defense, and Other Medicolegal and Economic Questions of Interest to Physicians

THE COMMON DRINKING CUP

One of the most significant features of the present campaign for better health conditions is the general and apparently spontaneous movement all over the country, against the use of common drinking cups, in railroad stations, trains, parks and public buildings. For years, the common cup has been the inevitable companion of the ice-water tank or fountain. Chained beside the water faucet, it might almost be said to be a national institution. But a sudden wave of public protest is rapidly sweeping it out of existence. The strange thing about this movement is that so little organized effort has been behind it, and that it is impossible to say exactly when or where the agitation for the abolition of the common drinking cup began. For these reasons, it is all the more gratifying, as an indication of growing public sentiment in favor of cleanliness and disease prevention. The substitution of individual glasses or of cheap temporary drinking utensils is so plainly in the interest of cleanliness and decency that but few of even the most confirmed conservatives have objected to this reform, nor has the most stubborn reactionary claimed that such legislation was inspired by selfish interests or due to the efforts of any "rings." The only explanation for the widespread general movement for the abolition of the common drinking cup is that the public became convinced that the common drinking cup was a filthy and disease-conveying utensil which belongs to an unsanitary past and that it should be dispensed with as soon as possible.

This campaign contains a lesson for those interested in progress in sanitary legislation and regulation. Education must precede legislation and regulation. Place the facts before the public in plain, every-day language, without exaggeration and with unmistakable proof, and the people will take care of the rest. Physicians and bacteriologists have for years known that disease could be transmitted by drinking vessels and that common drinking cups were a source of danger. These facts have become known to the general public and as soon as public opinion was educated to a sufficient point, legislation followed. These laws were not passed because physicians asked for them. The people did it.

A few extracts from recent papers are of interest in this connection. The Buffalo *Enquirer* grows philosophic and comments editorially:

"'What is one man's poison, signor, is anotner's meat or drink.' Likewise what is one period's improvement is another period's scorn.

"When an Erie train from Buffalo reaches the New Jersey line, the brakemen gather up the common drinking cups and put them out of reach and sight. When an Erie train starts from Jersey City, the cups are not in view. When the train crosses the New York line, the brakemen bring them from hiding and place them for use.

"It is law both ways. New Jersey, thoroughly down to date, has abolished the common drinking cup on railway trains. New York, a little slow, still requires by law, as a lawyer points out, that railroads shall supply water and drinking utensils to passengers. The common drinking cup is required by old law in New York, although it is forbidden by new law in New Jersey. So the Erie brakemen do the juggling act at the boundary line.

"No doubt it was considered a great blessing when the New York legislature decided to compel railways to supply a tank of water and a drinking cup on every passenger car. It was something over which to rejoice. Now, the drinking cup is a horror, a menace to health and life and its abolition is a measure of public safety.

"No doubt science and refinement will slaughter other customs. We do not know how vile and reckless we are until new revelations come along."

The Norfolk (Va.) *Pilot* says:

"It is a strange anomaly worthy the study of sociologists that sanitary reforms have to be forced on an unwilling, albeit an intelligent, people. . . . The common drinking cup must go, It is the dictum of all sanitary experts, physicians and students of public health. . . . As such abolition is not yet general throughout the states, as it doubtless soon will be, it has caused some inconvenience to passengers in interstate traveling. . . . Doubtless the railroads will shortly provide individual cups for passengers for the cost is infinitesimal and the inhibition of the 'cup of death' will soon obtain over a large section of the country if, indeed, it does not become the rule in every state. Convenient devices for obtaining individual cups at trifling cost are coming into use and it is a foregone conclusion that Virginia will not be far behind her sister states in adopting a system that makes for public health, refinement and civilization. The 'cup of death' must go."

Evidently the question has some theological aspects, as shown by the observation of the Peoria (Ill.) *Star*, which comments on the views of an Episcopalian bishop of Wisconsin:

"Bishop C. C. Grafton, of the Fondulac diocese, favors the action of the State Board of Health of Wisconsin exempting churches from the operation of the rule against the use of the common drinking cup. 'God prevents the transmission of disease through the use of the common communion cup,' says the good bishop. 'The good Lord would not permit the transmission of disease to any of His worshippers through the means of their worship of Him. There has never been an authentic case of the contraction of disease through the communion cup, though the common drinking cup elsewhere should be strictly forbidden.' In spite of the good bishop's belief, the use of a common drinking cup is filthy and should be abolished, whether at communions or elsewhere. God doesn't interpose to save people from their own foolish acts. Punishment follows the infraction of a natural law, whether the person be saint or sinner, and tuberculosis can be imparted from a common drinking cup to a deacon as soon as to a tramp."

The Bay City (Mich.) *Times* realizes that the reform is in the interest of cleanliness, good health and comfort:

"There is no dodging the issue. The private cup is the cup of peace. It is a movement in the direction of health. It is the outgrowth of a condition which medical science has demanded as a safeguard.

"And yet some people are heard objecting to the removal of the drinking cup from railroad trains and other places. If the public cup is a convenience, why not have a public handkerchief, a public towel, a public tooth brush and a public manicure set? One is as reasonable as the other, when you get down to brass tacks.

"Some city boards of health and some common councils that have not yet advanced very far in medical jurisprudence are holding back. The public drinking cup is an old friend and they are loath to part from it. It has served Tom, Dick and Harry, has accumulated germs and microbes, and a rare selection of tobacco juice, onion odors, contaminated saliva and what-not, and it ought to be respected. . . . These boards of health which have made a study of the dangers connected with the promiscuous use of a cup, are really getting so far advanced in their way of thinking that it may become advisable to hold a school of instruction or a conference, so that the kickers against abolishing the public cup, may be heard on this very important question. At such a school, the kickers might also have an opportunity for advocating the public tooth brush and the public towel, and especially the public handkerchief, all of which are closely related to, and allied with, the public drinking cup."

enteritis found. He states further that these parasites seem to be able to cause diarrhea in children. There seems to be no evidence that they may directly cause anemia.

References in the literature to the pathogenesis of *Trichomonas intestinalis* are not numerous. Hare's "Practice of Medicine," 1907 edition, says that it is not important from a clinical point of view. Anders' "Practice," 1909 edition, says that the organism is not important from a pathogenic standpoint. Ricketts and Dick, in the last edition (just issued) of "Infection, Immunity and Serum Therapy," 1911, say: "It seems to be of not much pathogenic significance but finds in the liquid stools and in alkaline reaction conditions which favor its proliferation. It may be transmitted as a contagion." This book gives Epstein as the authority for the latter statement. An article in The Journal, Oct. 15, 1910, p. 1377, by G. C. Dalley, assigns *Trichomonas intestinalis* as the only discoverable cause of a case of gangrene of the lung.

DOSAGE OF SODIUM BICARBONATE

To the Editor:—Hale found that caffein was useless and sometimes even harmful when given with acetanilid to antagonize its harmful effects, but that sodium bicarbonate lessens the toxicity of acetanilid. However, I have seen no mention of the amount or the dose that was best given for this purpose as determined by experimentation. Can you give me any light on this?

C. E. McReynolds, M.D., Goodrich, N. D.

Answer.—On writing to Dr. Hale, we learn that he is not able to answer definitely the questions concerning the relative doses of acetanilid and sodium bicarbonate, but that he believes, from his experimental work, that fairly large doses of the bicarbonate are indicated. He suggests at least 3 grains to every 2 of acetanilid. In case of poisoning he suggests giving as an antidote sodium bicarbonate in divided doses up to 15 or 30 grains, depending on the effect produced. He states that so far as he knows, his laboratory findings have not been put to test by clinical trial.

THE NOGUCHI AND MUELLER MODIFICATIONS OF THE WASSERMANN TEST

To the Editor:—What is the present status of the Noguchi modification of the Wassermann reaction? Is it considered as reliable as the Mueller modification? Can you give the Muèller technic or tell where it may be secured?

L. O. T.

Answer.—In the opinion of European authorities and some American, the Noguchi test is not so reliable as the original Wassermann. Many Wassermann workers regard it as not to be depended on alone. The Mueller modification is much more reliable. Its chief difference from the original Wassermann lies in the use of smaller amounts of the various reagents—a drop method. A consideration of the Mueller method will be found in the *Wiener klinische Wochenschrift*, 1907, No. 17, p. 514; 1908, No. 9, p. 282; 1909, No. 40, p. 1376.

The Public Service

Medical Department, U. S. Army

Changes during the week ended Aug. 26, 1911.

Van Poole, G. M., major, detailed to represent the Medical Department of the Army at meeting Association Military Surgeons of U. S., Milwaukee, Wis., September 26 to 30.

Clayton, George R., M.R.C., granted two months' and ten days' leave of absence.

Wilson, William H., major, granted fifteen days' leave of absence.

Brewer, Isaac W., M.R.C., granted one month and fifteen days' leave of absence.

Richard, Charles, colonel, granted thirty days' leave of absence.

Snyler, Henry D., lieut.-col., is detailed to represent the Medical Department of the Army at the meeting of the American Hospital Association to be held in New York City September 19 to 21.

Smith, Herbert H., M.R.C., granted ten days' leave of absence.

Patterson, Edwin W., M.R.C., on expiration of his present leave of absence ordered to Fort D. A. Russell, Wyo., for duty.

Appel, Daniel M., colonel, leave of absence extended one month.

Stone, Frank P., dental surgeon, returned to Presidio of Monterey, Cal., from temporary duty at Army General Hospital, San Francisco.

Eastman, William R., captain, relieved from duty as attending suurgeon, New York City, and ordered to Fort Riley, Kan., for duty.

Reed, George P., captain, granted thirty days' leave of absence.

Ford, Joseph H., major, so much of Par. 27, Special Orders No. 134, June 9, 1911, as relates to Major Ford, is revoked.

Brooke, Roger, major, on arrival at San Francisco, will report at General Hospital, Presidio of San Francisco, for duty.

Ashburn, Percy M., major, is ordered to Philippine Islands on transport Dec. 5, 1911, for duty on board, studying tropical diseases in the Philippine Islands.

Persons, Elbert E., major, relieved from duty as attending surgeon, Headquarters, Department of the East, and assigned to duty as attending surgeon, Eastern Division

Cutliffe, William O., M.R.C., is relieved from duty at Fort McIntosh, Texas, and will proceed to Fort Lawton, Wash., for duty as surgeon on transport *Dix*.

Bushnell, George E., colonel, is detailed to represent the Medical Department of the Army at annual meeting of New Mexico Tuberculosis Society at Las Vegas, September 6 to 9.

Lambie, John S., Jr., captain, on expiration of leave, will proceed to Fort McHenry, Md.

Robbins, Chandler P., major, is relieved from duty at Fort McHenry, Md., and will proceed to Fort Sill, Okla., for duty.

Duval, Douglas F., major, when relieved from duty at Fort Sill, will proceed to Fort Benjamin Harrison, Ind., for duty.

Suggs, Frank, M.R.C., having reported at Seattle, Wash., will proceed to Fort Lawton, Wash., for temporary duty.

Birmingham, Henry P., colonel, reports his departure, August 8, for Washington, D. C.

Casper, Joseph, first lieut., August 22, reports return from leave to sick in quarters this date, Fort Du Pont, Del.

Suggs, Frank, M.R.C., August 3, reports departure from Fort Egbert, Alaska, for Seattle, Wash.

Cooper, Wibb E., first lieut., August 5, reports departure for Manila on transport *Sheridan*.

Ferenbaugh, Thomas S., first lieut., August 16, reports departure from Langtry, Texas, for Barksdale, Texas, August 18, reports his arrival at Barksdale, Texas.

Gentry, Ernest A., first lieut., August 16, reports departure from Langtry, Texas, for Barksdale, Texas, August 18, reports arrival at Barksdale.

Usher, F. M. C., major, August 21, reports arrival at Fort Sam Houston, Texas, from Camp Mabry, Austin (Maneuvers Texas National Guard).

Pyles, W. L., captain, August 22, reports arrival at Fort D. A. Russell, Wyo.

Hall, J. F., captain, August 23, reports arrival at Fort Strong, Mass., for duty.

Denton, William, first lieut., August 21, reports arrival at Fort Sam Houston, from Camp Mabry, Austin, Texas (Maneuvers Texas National Guard). August 22, reports departure from Fort Sam Houston for temporary duty at Fort Bliss.

De Laney, Matthew A., major, granted leave of absence for one month to take effect about Aug. 24, 1911.

Medical Corps, U. S. Navy

Changes for the week ended Aug. 19, 1911.

Gatewood, J. D., medical director, commissioned medical director from July 11, 1911.

Gates, M. F., medical inspector, commissioned a medical inspector from July 11, 1911.

Shepard, G. W., P. A. surgeon, commissioned P. A. surgeon from Oct. 25, 1910.

Chambers, W., P. A. surgeon, commissioned P. A. surgeon from March 19, 1911.

Bacon, S., Melhorn, K. C., and McGuire, L. W., P. A. surgeons, commissioned P. A. surgeons from April 11, 1911.

Boland, M., P. A. surgeon, commissioned P. A. surgeon from July 12, 1911.

Phelps, J. R., and Clifton, A. L., P. A. surgeons, commissioned P. A. surgeons from July 15, 1911.

Henry, R. B., asst.-surg., detached from U. S. S. *Rainbow* and ordered to the naval hospital, Canacao, P. I.

Pratt, L. L., asst.-surg., detached from the naval hospital, Canacao, P. I., and ordered to the U. S. S. *Rainbow*.

Changes for the week ended Aug. 26, 1911.

Hoyt, R. E., surgeon, commissioned surgeon from June 11, 1911.

Jones, R. F., asst.-surgeon, commissioned assistant surgeon from Aug. 2, 1911.

Thomas, G. C., P. A. surgeon, detached from the navy recruiting station, Philadelphia, and ordered to the *Rhode Island*.

Schier, A. R., acting asst.-surgeon, appointed acting assistant surgeon from Aug. 16, 1911.

Donelson, M., P. A. surgeon, detached from the naval hospital, Newport, R. I., and ordered to the *Glacier*.

Dykes, J. R., P. A. surgeon, detached from the navy-yard, Portsmouth, N. H., and ordered to the naval hospital, Mare Island, Cal., for duty.

Diehl, O., medical director, commissioned medical director from July 20, 1911.

Lowndes, C. H. T., medical inspector, commissioned medical inspector from July 20, 1911.

Evans, S. G., surgeon, detached from the *Pennsylvania* and ordered home to wait orders.

Bachus, J. W., P. A. surgeon, detached from the *Iris* and ordered to the *Pennsylvania*.

Owens, W. D., P. A. surgeon, ordered to duty at the naval hospital, Newport, R. I.

Giltner, H. A., asst.-surgeon, detached from the *Glacier* and ordered to the *Iris*.

U. S. Public Health and Marine-Hospital Service

Changes for the week ended Aug. 16, 1911.

Pettus, W. J., assistant surgeon-general, granted twelve days' leave of absence from Aug. 15, 1911.

Irwin, Fairfax, surgeon, granted nineteen days' leave of absence from June 27, 1911, on account of sickness.

Magruder, G. M., surgeon, granted seventeen days' leave of absence from Aug. 13, 1911.

Ceddings, H. D., surgeon, leave of absence for one month from June 23, 1911, on account of sickness, amended to read twenty-one days.

Nydegger, J. A., surgeon, granted two months' leave of absence from July 24, 1911.

Francis, Edward, P. A. surgeon, granted one day's leave of absence July 31, 1911; granted seven days' leave of absence from Aug. 11, 1911, under paragraph 191, Service Regulations.

Ebersole, R. E., P. A. surgeon, granted eight days' leave of absence from Aug. 5, 1911, under paragraph 191, Service Regulations.

Pettyjohn, Jos., P. A. surgeon, granted one month's leave of absence from Aug. 16, 1911.

Ashford, F. A., P. A. surgeon, granted one month's leave of absence from Aug. 17, 1911.

Preble, Paul, asst.-surg., granted one month's leave of absence from Aug. 14, 1911.

Grimm, R. M., asst.-surg., directed to proceed to Pineville, Ky., via Columbia, S. C., on special temporary duty.

Kolb, L., asst.-surg., granted seven days' leave of absence from Aug. 11, 1911, under paragraph 191, Service Regulations.

Boyd, Frank, A. A. surgeon, granted twenty-six days' leave of absence from Aug. 6, 1911.

Watson, Harry J., A. A. surgeon, leave of absence for thirty days from Aug. 14, 1911, amended to read thirty days from Aug. 2, 1911.

Wilbert, Martin I., technical assistant, detailed to represent the Service at the meeting of the American Pharmaceutical Association to be held at Boston Aug. 14 to 19, 1911.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POST-GRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

THE COMMON DRINKING CUP

One of the most significant features of the present campaign for better health conditions is the general and apparently spontaneous movement all over the country, against the use of common drinking cups, in railroad stations, trains, parks and public buildings. For years, the common cup has been the inevitable companion of the ice-water tank or fountain. Chained beside the water faucet, it might almost be said to be a national institution. But a sudden wave of public protest is rapidly sweeping it out of existence. The strange thing about this movement is that so little organized effort has been behind it, and that it is impossible to say exactly when or where the agitation for the abolition of the common drinking cup began. For these reasons, it is all the more gratifying, as an indication of growing public sentiment in favor of cleanliness and disease prevention. The substitution of individual glasses or of cheap temporary drinking utensils is so plainly in the interest of cleanliness and decency that but few of even the most confirmed conservatives have objected to this reform, nor has the most stubborn reactionary claimed that such legislation was inspired by selfish interests or due to the efforts of any "rings." The only explanation for the widespread general movement for the abolition of the common drinking cup is that the public became convinced that the common drinking cup was a filthy and disease-conveying utensil which belongs to an unsanitary past and that it should be dispensed with as soon as possible.

This campaign contains a lesson for those interested in progress in sanitary legislation and regulation. Education must precede legislation and regulation. Place the facts before the public in plain, every-day language, without exaggeration and with unmistakable proof, and the people will take care of the rest. Physicians and bacteriologists have for years known that disease could be transmitted by drinking vessels and that common drinking cups were a source of danger. These facts have become known to the general public and as soon as public opinion was educated to a sufficient point, legislation followed. These laws were not passed because physicians asked for them. The people did it.

A few extracts from recent papers are of interest in this connection. The Buffalo *Enquirer* grows philosophic and comments editorially:

> "'What is one man's poison, signor, is anotner's meat or drink.' Likewise what is one period's improvement is another period's scorn.
>
> "When an Erie train from Buffalo reaches the New Jersey line, the brakemen gather up the common drinking cups and put them out of reach and sight. When an Erie train starts from Jersey City, the cups are not in view. When the train crosses the New York line, the brakemen bring them from hiding and place them for use.
>
> "It is law both ways. New Jersey, thoroughly down to date, has abolished the common drinking cup on railway trains. New York, a little slow, still requires by law, as a lawyer points out, that railroads shall supply water and drinking utensils to passengers. The common drinking cup is required by old law in New York, although it is forbidden by new law in New Jersey. So the Erie brakemen do the juggling act at the boundary line.
>
> "No doubt it was considered a great blessing when the New York legislature decided to compel railways to supply a tank of water and a drinking cup on every passenger car. It was something over which to rejoice. Now, the drinking cup is a horror, a menace to health and life and its abolition is a measure of public safety.
>
> "No doubt science and refinement will slaughter other customs. We do not know how vile and reckless we are until new revelations come along."

The Norfolk (Va.) *Pilot* says:

> "It is a strange anomaly worthy the study of sociologists that sanitary reforms have to be forced on an unwilling, albeit an intelligent, people. . . . The common drinking cup must go, It is the dictum of all sanitary experts, physicians and students of public health. . . . As such abolition is not yet general throughout the states, as it doubtless soon will be, it has caused some inconvenience to passengers in interstate traveling. . . . Doubtless the railroads will shortly provide individual cups for passengers for the cost is infinitesimal and the inhibition of the 'cup of death' will soon obtain over a large section of the country if, indeed, it does not become the rule in every state. Convenient devices for obtaining individual cups at trifling cost are coming into use and it is a foregone conclusion that Virginia will not be far behind her sister states in adopting a system that makes for public health, refinement and civilization. The 'cup of death' must go."

Evidently the question has some theological aspects, as shown by the observation of the Peoria (Ill.) *Star*, which comments on the views of an Episcopalian bishop of Wisconsin:

> "Bishop C. C. Grafton, of the Fondulac diocese, favors the action of the State Board of Health of Wisconsin exempting churches from the operation of the rule against the use of the common drinking cup. 'God prevents the transmission of disease through the use of the common communion cup,' says the good bishop. 'The good Lord would not permit the transmission of disease to any of His worshippers through the means of their worship of Him. There has never been an authentic case of the contraction of disease through the communion cup, though the common drinking cup elsewhere should be strictly forbidden.' In spite of the good bishop's belief, the use of a common drinking cup is filthy and should be abolished, whether at communions or elsewhere. God doesn't interpose to save people from their own foolish acts. Punishment follows the infraction of a natural law, whether the person be saint or sinner, and tuberculosis can be imparted from a common drinking cup to a deacon as soon as to a tramp."

The Bay City (Mich.) *Times* realizes that the reform is in the interest of cleanliness, good health and comfort:

> "There is no dodging the issue. The private cup is the cup of peace. It is a movement in the direction of health. It is the outgrowth of a condition which medical science has demanded as a safeguard.
>
> "And yet some people are heard objecting to the removal of the drinking cup from railroad trains and other places. If the public cup is a convenience, why not have a public handkerchief, a public towel, a public tooth brush and a public manicure set? One is as reasonable as the other, when you get down to brass tacks.
>
> "Some city boards of health and some common councils that have not yet advanced very far in medical jurisprudence are holding back. The public drinking cup is an old friend and they are loath to part from it. It has served Tom, Dick and Harry, has accumulated germs and microbes, and a rare selection of tobacco juice, onion odors, contaminated saliva and what-not, and it ought to be respected. . . . These boards of health which have made a study of the dangers connected with the promiscuous use of a cup, are really getting so far advanced in their way of thinking that it may become advisable to hold a school of instruction or a conference, so that the kickers against abolishing the public cup, may be heard on this very important question. At such a school, the kickers might also have an opportunity for advocating the public tooth brush and the public towel, and especially the public handkerchief, all of which are closely related to, and allied with, the public drinking cup."

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Iowa: Capitol Building, Des Moines, September 19-21. Sec., Dr. Guilford H. Sumner.

Massachusetts: State House, Boston, September 12-14. Sec., Dr. Edwin B. Harvey.

Missouri: Kansas City, September 25-27. Sec., Dr. Frank B. Hiller, Jefferson City.

New York: September 26-29. Mr. Harlan H. Horner, Chief of Examinations Division, Department of Education, Albany.

Constitution of the Association of American Medical Colleges

In the Educational Number of The Journal (Aug. 19, 1911) the Constitution of the Association of American Medical Colleges was published showing the various amendments which have been made from time to time since April 10, 1905. We discover, however, that Section 6, of Article 3, as printed shows that among other subjects, credit was allowed for "24 hours in osteopathy." Lest some captious reader may charge the Association with undue liberality in its allowance of credits, we hasten to say that the statement is due to a typographical error and that the clause should have read "24 hours in osteology." Further down the page is printed the section as it is now in force. This reads as follows: "Section 6.—No time credit shall be given to holders of a Bachelor's degree, but subject credit may be given on satisfactory examination. Four years of residence in a medical college shall be required of all candidates for the degree of Doctor of Medicine."

Book Notices

American Mineral Waters: The New England States. By W. W. Skinner, Chief, Water Laboratory. With a Chapter on Bacteriological Methods by G. W. Stiles, Jr., Bacteriological Chemist. Prepared Under the Direction of J. K. Haywood, Chief, Miscellaneous Division. Bull. 139, Bureau of Chemistry. U. S. Department of Agriculture. Paper. Pp. 111. Washington: Government Printing Office, 1911.

It is a valuable piece of work to take up American mineral waters in detail and give the chemical composition and the results of sanitary analysis and an inspection of the premises. The present bulletin covers only the springs of the New England States. The waters are classified according to their chemical character. Fortunately for the mineral water user, the organic purity of the waters of most of these springs is evident from the report of the analyses. In a few cases the water is reported to be of doubtful purity or the surroundings are said to suggest the possibility of contamination. In a few cases the presence of gas-forming bacilli in 1 c.c. of the water is noted, but the spring is not condemned on this account. The comments thus made should be a warning to the owners of such springs to remove objectionable features if they wish to sell their water. The report will be a valuable aid to the physician in selecting a mineral water, as he no longer needs to depend on the advertised analyses which were in most cases reliable, but in some cases failed to agree with the findings of the government chemists.

A List of Books on the History of Science, the John Crerar Library. January, 1911. Prepared by Aksel G. S. Josephson, Cataloguer. Paper. Pp. 297. Chicago, 1911.

The purpose of this list is to render easy the finding of the important classes of books with which it deals and the titles of which are now scattered through the public card catalogue. The list includes the social, physical, natural and medical sciences. It is gratifying to know that the John Crerar Library is especially rich in works on the history of the sciences of medicine. The material is well arranged. There is a complete index and the table of contents shows, at a glance, the groupings of the titles. The list is a distinct contribution to the bibliography of the history of science and will be of great value to students of that history and especially to the students of medical history, the interest in which is steadily increasing.

Infection, Immunity and Serum Therapy in Relation to the Infectious Diseases of Man. By H. T. Ricketts, M.D., Late Assistant Professor of Pathology, University of Chicago. Second Edition. Revised and Enlarged by the Author and by George F. Dick, M.D., Instructor in Pathology, University of Chicago, with Preface by Ludvig Hektoen, M.D. Cloth. Price, $2. Pp. 785. Chicago: American Medical Association, 1911.

The first edition of this work appeared in 1906; as a result of more recent progress along immunologic lines, a thorough revision became desirable, and in this Dr. Ricketts was engaged at the time of his death from typhus fever, contracted in the course of his work on that disease. The revision thus left unfinished has been completed by Dr. Dick, of the department of pathology of the University of Chicago.

The new edition presents several distinct advances over the old. An entirely new part is devoted to the principles of infection; in this are discussed in some detail not only the more general aspects of the subject, but the various mechanisms taking part in the conveyance of disease. A second part is devoted to the discussion of the principles of immunity, and a third to the special features presented by individual diseases. Each of these parts shows considerable elaboration over the corresponding part of the earlier edition—an elaboration necessitated by the new phases of the subjects that have been recently developed. Thus in the second part new chapters have been devoted to the subjects of complement deviation, opsonins and anaphylaxis, and in the third the discovery of spirilla as an important cause of disease has resulted in the introduction of a new etiological group.

The work as a whole presents a thorough summary of our present knowledge of the problems of infection and immunity. The condensation necessary to cover so large and intricate a subject in the limits of a volume of moderate dimensions has not resulted in an unduly dogmatic form of presentation, and as a rule disputed problems are presented with clarity and discretion. As a comprehensive survey of a subject whose literature is so scattered as to be ordinarily inaccessible, the work occupies a distinct and very valuable place. Not only is this true for the practicing physician who may wish to keep abreast of recent developments along these lines, but as well for the special worker who desires to obtain a more general view of his subject.

Die palpablen Gebilde des normalen menschlichen Körpers und deren methodische Palpation. Nach eigenen Untersuchungen an der Leiche und am Lebenden von Dr. Toby Cohn, Nervenarzt in Berlin. III Teil: Hals und Kopf. Paper. Price, 8 marks. Pp. 585, with 92 illustrations. Berlin: S. Karger, 1911.

The present pamphlet of 200 pages is the third of a series, the first two covering 380 pages, and dealing respectively with the upper and lower extremities. The work is the result of an exhaustive study both of the cadaver and of the living subject and when completed will cover, as no other work does, the surface anatomy and its normal variations, of the whole body as it presents itself to the examining eye and finger. By his clear style and broad grasp and presentation, of what might seem a very dry subject, the author has made a very interesting as well as a valuable contribution to medical science. The internist, the neurologist, the pediatrist, the dermatologist and any other specialist will find the work of nearly the same interest and practical value as will the surgeon. The work is in a class by itself and merits the warmest commendation.

Mysteries of Life Series. By Isabelle T. Smart, M.D., Medical Examiner of Defective Children, Department of Education, City of New York. Book 1: What a Mother Should Tell Her Little Girl. Pp. 105. Book 2: What a Mother Should Tell Her Daughter. Pp. 105. Book 3: What a Father Should Tell His Little Boy. Pp. 116. Book 4: What a Father Should Tell His Son. Pp. 103. Cloth. $2.50 per set; 75 cents per volume. New York: The Bodmer Publishing Co., 1911.

This series of four little books is another evidence of the awakening interest of the public in instruction along all lines which lead to better health conditions. The number of books recently published on sex hygiene is an evidence both of the need and of the demand for adequate instruction on this subject. The duty of the conscientious parent to afford some kind of knowledge to the growing child is evident. The question as to the form such instruction shall take should be determined in each case by the parent. The number of books available for this purpose is rapidly increasing and this set should be considered in selecting suitable material.

Medicolegal

Liability for Malpractice in Delivery with Instruments—Skill Required

(Kline vs. Nicholson (Ia.), 130 N. W. R. 722.)

The Supreme Court of Iowa in this case affirms a judgment for the defendant for $459 damages on a counterclaim for malpractice to the plaintiff's action for compensation. The court says that the allegations in the counterclaim of negligence submitted to the jury were that the plaintiff, in effecting the delivery of the defendant's wife during child labor, negligently used instruments; that in the negligent and unskilful use of the instruments he lacerated and wounded the defendant's wife; that he afterward treated such laceration in a negligent and unskilful manner; that in treating the wound he was so negligent and unskilful that he failed to properly dress the same, and that by such negligent and unskilful treatment the wound was prevented from healing.

There was evidence tending to show that the plaintiff used forceps in effecting delivery without waiting a sufficient time to see whether by his assistance delivery could not have been effected without the use of such an instrument, and that, as the use of instruments was more likely to result in rupture involving the danger of subsequent operations, the plaintiff proceeded in a negligent manner. The court is justified in construing the allegation as to negligent use of instruments when in the exercise of reasonable care and judgment they should not have been used as well as the use of instruments as and when they were used. If the defendant's testimony was to be believed, the plaintiff used defective instruments; that is, forceps tied together after they were adjusted on the head of the infant with a string, rag, or piece of silk, with the result that the fastening broke and allowed the forceps to pull loose, causing a rupture of the parts, when, if the forceps had been of a proper kind or properly fastened, such result would not have followed. The evidence tended to show that the plaintiff used an amount of force and violence in attempting to extricate the infant from its mother's womb which was unnecessary and improper, resulting in unnecessary injuries to the patient, including rupture of the perineum and sphincter muscle. The evidence also tended to show an improper method of treatment after the rupture occurred with the result that injury has not been entirely repaired. The court reaches the conclusion that, under the evidence, there was no error in submitting the question of the plaintiff's negligence to the jury, nor in submitting to them each of the allegations of negligence as they were submitted.

The contention for the plaintiff running through the various divisions of his argument relating to the sufficiency of the evidence seemed to be that if he, having the knowledge and skill required in the practice of his profession, erred only in his judgment as to whether instruments should not at the time have been used in effecting delivery and in the method of using instruments to effect delivery, he was not liable for the reason that his duty was only to exercise reasonable care and judgment. But it was still for the jury to say under proper instructions whether, conceding the plaintiff to possess the requisite knowledge and skill, he did in the particular case use the care and judgment which as such a physician he ought to have used. If he was careless or did not use the judgment which a competent physician would ordinarily use under the circumstances of the case, then he was liable in damages. These questions were to be determined, of course, in the light of expert evidence as to what a reasonable, judicious and careful physician would do under like circumstances; but it was for the jury to say whether, in the light of the expert evidence, the plaintiff did exercise the care, skill and judgment required.

In three different instructions the jury were told in effect that, if the plaintiff possessed and employed in the treatment of the defendant's wife such reasonable skill and diligence as were ordinarily exercised in his profession at and in localities similar to that in which he practiced, then he was not responsible for the result of the operation. That statement of law was in accordance with the decisions of this court. But in one instruction the law was thus stated: "Negligence in this case as applied to plaintiff consists in the doing by plaintiff, in the treatment of the defendant's wife, of some act that a physician and surgeon possessing and exercising the average skill and care of the medical profession in the vicinity of the defendant's residence would not ordinarily do under like circumstances." This the plaintiff complained of on the ground that by it he was required to possess and exercise the care and skill usually possessed and exercised in the vicinity of the defendant's residence, rather than that usually possessed and exercised in similar localities. It might be that under some circumstances the rule as thus stated would be erroneous and prejudicial. But, unless the jury might have been led to exact of the plaintiff a higher standard of skill and care than required in similar localities, then he could not possibly have been prejudiced by the instruction, and that did not appear in this case. As supporting the view that such an instruction as above quoted, though erroneous, may be non-prejudicial in a case where the physician is appealing from a judgment against him, see Dunbauld vs. Thompson, 109 Iowa, 199.

Contract of Physician for Part of Amount Recovered by Injured Person Not Valid

(Sherman vs. Burton (Mich.), 130 N. W. R. 667.)

The Supreme Court of Michigan holds invalid a contract made by the defendant with the plaintiff, a physician, whereby the former agreed to pay to the latter, for professional services, one-third of any sum which the former might receive from an electric railway company as damages, arising out of an injury, and further agreed to pay to the physician the sum of $90, in addition to said one-third, if the amount received was $2,000 or more, that is, if the settlement was made outside of courts. The court says it thinks that it necessarily followed from the circumstances of the case as disclosed and the agreement that the parties contemplated that the physician should be a witness in case of suit, and should give a history of, and opinion on, the case in the event of a proposed settlement. His interest in the amount of the damages furnished a powerful motive for exaggeration, suppression, and misrepresentation, a temptation to swell the damages so likely to color his testimony as to be inimical to the pure administration of justice, so that the agreement must be held void.

1. **Peritoneal Adhesions.**—During the course of an operation for the relief of an enormous post-operative ventral hernia a situation arose which suggested to Richardson a new method of dealing with denuded bowel surfaces under certain conditions. After effecting the release of the intestine there remained two extensive raw areas, each measuring 2 to 3 inches in length, involving nearly one-half the circumference of the bowel, and separated from each other by 6 or 8 inches of practically normal intestine. The problem was practically solved by the accidental laceration and partial retraction of one leaflet of the mesenteric peritoneum just along its line of attachment to the bowel and adjacent to one of the raw areas on the surface of the latter, which occurred during its

separation from the hernial sac. There being a considerable deposit of fat between the two layers of mesenteric peritoneum, it was a simple and easy procedure to extend the separation of the torn leaflet and its attached fat in all directions from the underlying vessels and the opposite intact leaflet with its fat, thus obtaining a large, movable flap of normal peritoneum which was easily drawn up, without tension, spread out over the raw surface on the bowel, and tacked down with a few fine silk sutures. The result was satisfactory in every way. The patient's recovery was complete.

This experience led Richardson to investigate the idea further in order to determine accurately its limitations and to meet certain theoretical objections. His conclusions, based on such a study, are as follows: 1. The procedure is best applicable to that portion of the intestinal tract when, in such cases as the one described, present methods are inadequate, namely, from the upper jejunum to the lower ileum. It may be rationally applied, however, to any portion of the bowel possessing a mesentery of sufficient length to admit of its ready execution. 2. Care must be exercised at the duodenum, upper jejunum and lower ileum not to produce kinks of the bowel. 3. In cases exhibiting a scanty deposit of fat in the mesentery, plication is a rapid, safe and efficient substitute for separation of the two peritoneal leaves. 4. Aside from a slight spiral rotation, which in view of peristalsis and the mobility of the parts is entirely insufficient to produce obstruction, the procedure has no demonstrable effect on the bowel lumen. 5. It can safely be extended to include nearly one-half the circumference of the bowel and 3 to 4 inches in continuity. There is no apparent reason why it should not be repeated as often as necessary at different levels of the intestinal tract. 6. In view of the rich vascular anastomosis and the mobility of both the bowel and its mesentery, if care be exercised in placing the sutures so as to avoid the trunk vessels, the effect on the circulation is negligible. 7. Stability and permanence of the coaptation is readily secured through intelligent disposition of the sutures.

3. **Puerperal Infection with Isolation from Uterus of B. Influenzæ.**—A simple laboratory method for making a hemoglobin or blood medium capable of growing the *B. influenzæ*, is the following worked out by Thalhimer. Freshly-drawn beef blood obtained from an abattoir is collected in a wide-mouthed jar and defibrinated by shaking with a number of medium-sized marbles. This is laked by adding an equal part of distilled water and rendered free from bacteria by passing through a sterile Reichel filter as above. This yields a beautiful, clear, red fluid and 20 to 30 c.c. of this are added to 1 liter of sterile melted agar at 45 C. and poured into sterile tubes. The medium which results is also perfectly clear, bright red and of the same density of color as ordinary blood-agar. On this medium two organisms which were unsuccessfully tested on the hemoglobin agar, were successfully passed through ten subcultures by Thalhimer. The growth occurred in twenty-four hours, and was typical of the *B. influenzæ*, occurring in small, discrete, dewdrop colonies. Smears showed the typical morphology. Pneumococcus, streptococcus, *Streptococcus mucosus* and gonococcus also grew luxuriantly. This method is a modification of former methods, notably that of Pfeiffer, and is believed to be the simplest yet devised for making blood-agar. Its chief advantage over that of Pfeiffer is that the laking agent is one which does not interfere with growth of bacteria and does not have to be removed. From 40 to 50 c.c. of this laked blood can be filtered in twenty-four hours through a Reichel filter of 50 c.c. capacity. Should a larger quantity be needed a larger filter can be used. It is evident that the hemolytic qualities of an organism cannot be tested with this medium.

4. **Hyperleukocytosis in Bronchopneumonia.**—At the first count made by Austrian in this case the leukocytes numbered 130,000 per c.mm. Seven hours later, the leukocytes were 144,000 per c.mm.; on the following morning they hal increased to 183,000 per c.mm. and that evening reached a maximum of 206,000 per c.mm. During the following four days they varied between 126,000 and 156,000, but with the onset of a mastoiditis again rose to 192,000 per c.mm.

14. **Hyperthyroidism.**—There is no doubt at all in Stern's mind that many cases which, in a slipshod manner, are designated as neurasthenia or hysteria, are expressions of acute or chronic thyrotoxicoses. He says that a minor case of hysteria and an early or mild thyrotoxic state have many symptoms in common. Some of the rarer hysterical phenomena, as hysterical fever, or hysterical tremor together with accelerated cardiac activity, clinically viewed, appear to be the immediate result of hyperthyroidism. Elevation of temperature is one of the early, if not the earliest, objective symptoms of many instances of hyperthyroidism. It seems to be a much more constant manifestation in the mild than in the more pronounced instances of the affection. In many cases the mouth temperature is raised but 1 degree, or a fraction thereof; in others the increase amounts to 2 or even 3 degrees. In some cases the temperature fluctuates, with occasional intermissions, between 99 and 99.4 F. for months and even years; in others, the slightest exertion or excitement drives it up from 99 to 100 F., or thereabouts. In a majority of instances the lowest temperature is recorded after a night's rest; continued rest in bed will occasionally reduce the temperature to normal for a brief period. The usual discrepancy of about ½ degree F. between the mouth and rectal temperatures does not exist in all cases; in some cases the discrepancy is less than 0.3 degree, and in a few there does not seem to prevail any discrepancy at all. Tyrotoxic temperature elevation never reaches the extreme height of hysterical fever, but it is enduring for a longer period. While there generally ensues a rapid decline of hysterical pyrexia, the slight thyrotoxic temperature increase abates slowly, as a rule. Like the fever of hysteria, however, that of hyperthyroidism may start abruptly, and like the former it is liable to appear, or to become augmented, in the wake of any exertion or excitement. Hysterical pyrexia may be differentiated from thyrotoxic temperature elevation by the following three main factors, viz.: Hysterical fever does not, as a rule, concur with physical decline and emaciation, thyrotoxic temperature elevation usually does; the urine in instances of hysteric fever exhibits a small urea and phosphoric acid quotient, whereas in the presence of hyperthyroidism it is increased; hysteric pyrexia is usually not influenced by the administration of preparations of thyroid or iodin, while these drugs are liable to prolong or aggravate the thyrotoxic fever.

19. **Tube-Casts and Pseudo-Casts.**—Heitzmann emphasizes that a diagnosis of the presence of true tubular casts in the urine should under no circumstances be based on the findings of cast-like structures alone. Such structures must always be associated with other evidences of a pathologic condition, such as red blood-corpuscles, leukocytes or pus corpuscles and epithelia from the uriniferous tubules, before the diagnosis of a tube cast becomes admissible.

23. **Tuberculosis of Mucosa of Hard Palate.**—A man suffering from a pronounced pulmonary tuberculosis about two years ago noticed a small red spot on the right side of the palate about ¼ inch behind the posterior border of the palate. It increased somewhat in size, was extraordinarily painful and refused to heal after becoming ulcerated. He consulted a physician who, after treating it for a while, told him that he could not do any more for him. Another colleague cauterized it with nitric acid. It disappeared after being treated for some time. About four months ago it reappeared, spreading rapidly; it was then that he consulted Dittrich. During all this time he felt good and worked every day. He showed the following condition: On either side of the median line there were aggregations of small papules of the size of pin heads which were somewhat acuminate, only little inflamed, did not bleed on touch, and were separated by a deep median furrow. They were more marked on the right than on the left side. The lesions were sharply defined anteriorly and merged into the tissues posteriorly with but very slight inflammatory reaction. Behind the anterior border there was an ulceration on either side of the furrow; the one on the left was the larger in size. These ulcerations were triangular in shape, had irregular margins, were superficial and spreading peripherally. Their bases were red, painful and slightly bleeding on touch and were very little indurated, with margins that were only moderately inflamed and covered with a dirty grayish material. They were first touched with 25 per cent. lactic acid, but when this failed to make an impression, 95 per cent. phenol (carbolic acid) was resorted to. While the right ulceration responded to the application of phenol and disappeared soon, the left one showed a decided tendency to spread and proved to be very recalcitrant. The ulcers finally disappeared leaving very little scar tissue and a somewhat tunicated condition of the mucous membrane, the papular, i. e., tubercular condition, spread laterally, at last almost touching the alveolar processes. The microscope showed the following: the epithelium presented a moderate amount of edema. In the connective tissue directly beneath the epithelium were distinct, isolated collections of small, round cells, in the center of which giant cells were discerned.

40. **Oudin Current for Bladder Tumors.**—Beer has treated successfully up to date five cases of primary papillary tumors of the bladder, aggregating nine distinct tumors, with this new method. In addition he has treated two cases of recurrent papillary tumor of the bladder. One patient is still under treatment, and a large part of the very extensive growth has been thrown off. The original tumor was excised some years ago and was diagnosed as carcinoma by a competent pathologist. The other recurrent case could not be treated adequately, as the old suprapubic wound opened up and the patient gradually developed a fatal renal insufficiency. As the result of one treatment in this case, larger pieces of the papillary growth sloughed away, as in all the other cases. In two undoubted cases of carcinoma of the non-papillary type results were negative. Beer introduced the Oudin current through a catheterizing cystoscope. In the case of a patient 81 years old the condition was considered inoperable. The large papillary growth made up of three confluent tumors surrounded the right ureter. To remove the growth and reimplant the ureter would have been too severe a strain for this anemic old woman. In eight seances aggregating thirteen and a fourth minutes' application of the Oudin current, the tumor was painlessly destroyed and the patient has been completely restored to health. There is no sign of recurrence. In a second case there was a fair-sized sessile growth which was bleeding very actively. The very first application and the very first treatment controlled this, so that the urine was absolutely clear twelve hours after the treatment and has remained so ever since. There is no sign of recurrence.

55. **Lupus Erythematosus.**—That the disease is not tuberculous *per se*, is evident to Friedlander, but the question as to whether it is due to a tuberculous or other toxin, he says, is not so clear. Probably the truth lies somewhere between the two extremes; that is to say, that the disease is caused by a toxin, carried by the blood, as evidenced by the fact that the blood-vessels are the first structures to be affected, and while tuberculosis or a tuberculous inheritance may predispose to lupus erythematosus by lowering the general resistance, it is certainly more of a predisposing than a causative factor. That it is a constitutional affection is clearly shown in those cases which pass over into the acute fulminating type, in which the patient shows all the symptoms of a profound toxemia with involvement of various internal organs, especially the kidneys; but the cause of the toxemia cannot be laid to any single toxin. That feeble or deranged circulation, trauma and irritation, are factors in the causation of this affection is also evident, but whether the toxemia precedes the local irritation and the external lesion is the exciting factor, or whether the skin damage by the external lesion presents less resistance than the remaining cutaneous envelope to the circulating factor, is a question to be determined.

76. **Pure Cultivation of Treponema Pallidum.**—Noguchi reports the positive reproduction of syphilitic lesions in rabbits by means of pure cultures of *Treponema pallidum.* He employed the spirochete-containing testicular tissue of rabbits which had been inoculated with human syphilitic material for the purpose of cultivating the pallidum. The culture medium used was a serum water (sheep, horse, rabbit) to which a piece of sterile rabbit tissue is added. The rabbit tissues best adapted to this purpose are the kidney and testicle. The heart muscle is also good, but liver is unsuitable, since it is not only difficult to obtain in a sterile condition, but even when sterile, supplies enough carbohydrates to render the medium strongly acid in cases in which certain bacteria are simultaneously cultivated. Strict anaerobic conditions are very important in obtaining the first generation of pallida. To obtain the first generation of the *Treponema pallidum* in virulent form, the following conditions are essential: (1) the presence of suitable fresh sterile tissue in serum water; (2) strict anaerobiosis; (3) a slightly alkaline reaction as furnished by the serum and tissue, and (4) a temperature of about 35 to 37 C. The presence of agar or gelatin seems to interfere with the successful growth of the first generation of the spirochetes. On the other hand, when once adapted to the artificial serum-water tissue medium, the pallidum grows well under less strictly anaerobic conditions. In fact, certain strains even grow well in a medium containing agar, provided that suitable fresh tissue is placed low down in a high column of medium (serum-water or serum-agar), and that it is covered with paraffin oil. Certain pallidum strains refuse to grow in a solid medium for several generations, and none of Noguchi's pallidum strains grew in any medium without the presence of tissue. Thus all the pure pallidum strains are being cultivated in a tissue-containing medium. Out of ten strains of *Treponema pallidum,* six have been cultivated in the serum-water tissue medium. Except in one instance, the pallidum has grown together with other bacteria. So far only two strains of pure cultures have been carefully tested for their virulence. Both strains have produced typical lesions in the testicle of the rabbit.

77. **Phagocytic Immunity in Pneumococcus Infections.**—Strouse endeavored to show through animal experiments, that phagocytic immunity is to a high degree specific for the organism used in immunization, and that the amount of opsonin produced in the process depends to a great extent on the virulence of the organism. The negative results obtained with post-critical sera do not mean that opsonins may not be present (five positive cases indicated their presence), but they emphasize strongly the fact that they are not formed to any great extent. Therefore, this study adds further support to the view that although opsonic immunity is produced in pneumonia, it is not the only means of defense possessed by the body, and by itself it cannot explain the crisis.

78. **Infection of Rabbits with Virus of Poliomyelitis.**—The experimental results obtained by Marks would, it seems, leave no doubt that the virus of poliomyelitis can be propagated in certain individual rabbits, at least through a limited series of inoculations. They also show that the virus is not confined to the central nervous system in these animals, but occurs, perhaps in equal amount, in other organs—certainly in the liver and spleen.

79. **Double Nephrectomy and Replantation of One Kidney.**—A dog, after having undergone a double nephrectomy and the replantation of one kidney lived in excellent health for almost two and a half years. She died of an intercurrent disease which was without relation to the operation. The autopsy showed the kidney to be normal. Hence Carrel says the experiment proves definitely that the extirpation of the kidney in the dog, its perfusion with Locke's solution, the complete interruption of its circulation for fifty minutes, and the suture of its vessels and ureter do not interfere with its functions, even after a long period of time, and it indicates that from a purely surgical standpoint, the grafting of organs is a real possibility.

80. **Patching of Abdominal Aorta with Rubber.**—In two recent experiments Carrel attempted to patch an artery with inorganic and organic foreign substances in order to ascertain whether they can be used in the reparation or in the permanent intubation of large vessels. Under ether anesthesia a segment of glass tubing, about five centimeters long, coated with paraffin was introduced into the abdominal aorta of a dog. The pulsations of the femoral arteries remained normal. Six days after the operation, the animal was allowed to run. Paralysis of the posterior limbs developed and the pulsation of the femoral arteries disappeared. It was thought that the glass tubing had been displaced by the movements of the animal and that coagulation had occurred. Laparotomy was performed, the tube extirpated, and the aortic circulation reestablished. The glass tubing was obliterated by a soft clot of recent formation. But it was found that the glass wall, inside of which circulation had taken place for six days, was covered by a thin, whitish membrane. A tube having the appearance of a thin-walled artery could be extracted from the glass tubing. Microscopic examination showed that it was composed of a dense fibrin infiltrated by many leukocytes. Carrel thinks it is probable that if the dog had been quiet and the glass tubing had not been displaced, the fibrinous

tube would have become organized and would have formed inside of the glass tubing a new intima, in the manner of the canalization of a dissecting aneurism. In the second experiment, a piece of the anterior wall of the abdominal aorta was resected and replaced by a piece of rubber.

Experiment.—A medium-sized male dog. Feb. 7, 1910, 9:45 a. m., under ether anesthesia, transversal laparotomy; intestines wrapped in greased silk towels and a wool blanket. 10:05 a. m., dissection of the abdominal aorta below the renal arteries. Interruption of the circulation by two Crile forceps placed about 4 cm. from each other. Resection of a small piece of the anterior wall of the aorta. The opening was about 20 mm. long and 12 mm. wide. It was patched by a piece of thin rubber. At 10:36 a. m., the circulation was reestablished. There is some leakage at the line of suture, which is easily controlled by a few stitches. The abdomen is closed and the operation completed by 11:00 a. m. After the operation, there was no modification of the femoral pulse, and the animal remained in excellent health. May 26, 1911, the femoral pulse and the aortic pulsations were normal. There was a slight thickening of the anterior wall at the level of the patching, and the artery adhered to the thoracic duct. About fifteen months later the aortic segment bearing the rubber patch was extirpated and examined. The lumen of the vessel was normal; the wall was thickened. On the external side of the aorta there was no evidence of the patch, and the adventitia was thicker than normally. The intima was smooth and glistening. The piece of rubber was present in the wall. On its external side, a new adventitia had developed, while its internal side was covered by a thick layer of internal tissue. The experiment indicates, therefore, that a foreign inert substance, under certain conditions, does not produce an obliterative thrombosis, but can, indeed, be used in the reparation of the wall of a large artery.

82. **Immunity in Cancers of White Rat.**—Levin concludes that immunity to cancer growth is due to an active inhibitory influence of some substance present in the body fluids of the immune host, and not to any purely cellular activity. Immunity to growth of cancer must be very similar to, though not identical with, immunity in bacterial disease.

103 *Double Dermoids and Pregnancy. W. P. Manton, Detroit.

95. **Malformations of Female Genitalia.**—In one case cited by Miller the malformation was a typical one of bicornuate uterus in which the septum had extended not only between the uterine chambers, but had also divided the vagina into two halves. A second case was one of congenital absence of uterus and vagina. Immediately below the external inguinal ring in the upper portion of the labium majus on each side was a small oval body the size of an ovary. These bodies were sensitive to pressure, but did not swell periodically and were not the seat of pain except on pressure. The inguinal canals were not patulous and there was no impulse on coughing. Miller took these bodies to be misplaced mal-developed ovaries. The case was apparently one of congenital absence of vulva, vagina, uterus and tubes, with misplaced rudimentary ovaries. The third case was one of pyocolpos due to atresia of the hymen. The fourth case was one of congenital atresia of the vagina and external os uteri. All of these patients were of the white race. Miller has seen only one congenital malformation in the negro race and that was of a minor character. It was a transverse septum not complete about halfway up the vagina.

99. **Eclampsia.**—In Prentiss' case there was a preeclamptic toxemia and postpartum eclampsia, the patient having one convulsion the day after delivery.

100. **Abstraction of Calcium Salts.**—Drennan says that if the abstraction of calcium salts from the mother's blood by the fetus is the cause of puerperal eclampsia in the former, then the eclamptic mother should not nurse her infant.

101. **Shock in Eclampsia.**—Bailey records certain observations made on six eclamptic and preeclamptic cases with special regard to the shock attendant on delivery and the shock caused by drugs used for the rapid reduction of blood-pressure. He found that rapid emptying of the uterus in eclampsia frequently produces a decrease in blood-pressure amounting to 100 mm. of Hg, causing a condition of collapse or shock. Veratrum viride given to its full physiologic effect may cause a drop of 145 mm. of Hg. in the blood-pressure, producing shock. The administration of veratrum viride combined with emptying the uterus in eclampsia may produce such profound shock that the patient cannot recover. While it is probable that the high blood-pressure of eclampsia is one of Nature's protective mechanisms, still if it is deemed advisable to lower it, nitroglycerin and erythrol tetranitrate should be used for their action is on the peripheral vessels and not on the medullary centers. One of the best means of temporarily lowering blood-pressure in antepartum or intrapartum eclampsia is the emptying of the uterus. The blood-pressure observations in Bailey's cases showed a marked hypotension immediately after delivery, and if it is deemed desirable to lower the blood-pressure in this disease, Bailey says, the best method would be the delivery of the child, but the question comes up as to the advisability of reducing blood-pressure in these cases. The system is nearly overcome by the circulation of some toxin or toxins and it is an open question as to whether the rise in blood-pressure is not one of Nature's protective mechanisms. If the blood-pressure is to be lowered why not dilate the splanchnic area without depressing the medullary centers. Dilation of this area is accomplished by an anemia of the brain which would be very desirable. Nitroglycerin, in 1/50 gr. dose, will depress the blood-pressure 11 to 14 per cent. within five minutes when given by mouth and action begins to take place within two minutes. Together with the nitroglycerin, 2 gr. of erythrol tetranitrate should be given because its action begins when the nitroglycerin action wanes and the depression of the blood-pressure is continued for about three hours. These drugs are especially active in high blood-pressure, and a single dose of each of them would bring the high pressure seen in these cases well within the limits of safety.

102. **Plaster Lace.**—Grad's method consists in coaptating the skin incision by lacing instead of suturing. To prepare the plaster lace two pieces of Z. O. adhesive plaster, 6 by 8 inches long, are pasted on a glass bottle 4 inches in diameter. Hooks used by dressmakers are then sewed to the edge of the plaster 1 inch apart. The flask with the plaster attached is then wrapped up securely and sterilized in a steam sterilizer. After the sterilization the plaster is ready for use. To facilitate the removal of the plaster, hot water is poured into the bottle, when the plaster can be stripped off from the glass easily. After the peritoneum and fascia are closed, the wound is dried and all bleeding stopped. The skin for 8 to 10 inches on either side of the wound is dried with ether. The plaster is then placed so that the hooks are an inch away from the edge of the skin incision and is made to adhere firmly to the

integument. With a suitable piece of sterile tape the lacing is begun in the center of the wound, as it is easier to close the wound smoothly if the lacing is begun in the center. The tension is adjusted so as to bring the edges of the wound in apposition, care being taken not to allow the edge of the skin to fold under or to overlap. The wound is then dried and a suitable dressing applied. Twenty-four hours later the wound should be inspected and the dressing changed, as it will be found that the gauze next to the skin is soiled by the drainage from the wound. The plaster lace is allowed to remain on the skin for some ten to twelve days, and in the meanwhile the wound can be inspected as often as may be desired. By the use of this method of closure the incision remains uncovered and admits of inspection at any time. The coaptation of the wound is under absolute control, as the tension of the wound can be regulated to a nicety. The scar is threadlike. There is no skin suturing and consequently no stitch abscesses.

109 *Narcotic Addiction and Its Treatment. E. W. Knowles, Greeley, Colo.
110 Case of Rheumatoid Arthritis of Almost Undoubted Syphilitic Origin. L. W. Ely, Denver.

109. **Narcotic Addiction.**—The following treatment has been used by Knowles for several years with good results: when the patient comes for treatment he is required to give up what morphin or other drugs he has with him, and he is given whatever drug he may need to make him comfortable during the first or primary stage. When the second or active stage is begun, the drug is withdrawn at once. On admission give one tablet of the following formula, at two-hour intervals until five are taken:

℞	Gm. or c.c.		
Hydrargyri chloridi *mitis*		13	gr.ii
Podophylli		01	gr.1/6
Phenolphthalein		06	gr.i
Atropinæ sulphatis		0003	gr.1/200
Strychninæ nitratis		0017	gr.1/40

Three hours after the last tablet has been taken give 5 ounces of a saturated solution of magnesium sulphate, or 3 ounces of castor oil. If the bowels do not move freely within two hours, repeat the dose. This Knowles has not found necessary unless the patient had loaded up *on morphin* before coming in. A high enema should be given a short time before starting the active treatment. It is absolutely necessary for the bowels to respond freely at this time. The treatment is discontinued until they do. Purging does these patients good instead of harm. During this stage *no food* is to be given until the bowels have been thoroughly emptied. After this a full tray may be given, and when this has digested the patient is ready for the active treatment.

From now on, Knowles says, the patient should be in bed, and the narcotic should be withdrawn. Give the patient hypodermically 8 drops of the following solution:

℞	*Gm. or c.c.*		
Hyoscinæ hydrobromatis		013	gr.1/5
Pilocarpinæ nitratis		12	gr.ii
Strychninæ nitratis		013	gr.1/5
Aquæ	16		ʒiv

Repeat the dose at half-hour intervals until the patient is asleep. This usually requires from two to three doses. On awakening repeat the dose, no matter how *comfortable* the patient feels. From now on govern the dose and time of giving by the patient's condition. Give enough to keep him asleep or quiet, or in a mild belladona intoxication. If this condition be kept up there is no suffering. The dose may have to be increased to 10, 12 or 15 drops, and the interval will vary from two to five hours. Never after the first sleep is it necessary to repeat the dose oftener than every two hours.

When the sleep becomes natural, and no nervousness, jerking or twitching of the muscles is present, the medicine may be stopped. This will require from sixty to ninety-six hours, depending on the condition, the daily dose and the duration of the addiction. Another important sign is that the patient acquires a tolerance for the prescription with the passing of the withdrawal symptoms. Green stools should appear at this time. When the patient awakens from his first sleep, which is from three to five hours after the hypodermic has taken effect, give 1 grain of calomel every three hours until 8 grains are taken, and at the end of the thirtieth hour give 3 ounces of castor oil or 5 ounces of a saturated solution of sulphate of magnesia, and repeat in two hours if free action is not obtained. At the end of the fifty-sixth hour repeat the dose of oil. When this acts the green stools should appear. If it be found necessary to continue the treatment beyond the seventy-second hour, give a like dose of oil or saline. It is important that the bowels move and move freely at these intervals. If this treatment be carried out to the letter, the patient should sleep through the entire time, only awakening to go to the toilet, or for his bath or to be given food.

Milk or other liquid food should be given at regular intervals during the entire active stage. Acids should be avoided as the stomach shows a hyperacidity. It is an excellent plan after the first twenty-four hours to give sodium bicarbonate every four hours, especially if there is a tendency to vomit. Hot tub baths are given every morning, followed by an alcohol rub. Hot packs may be given to the strong and robust to help elimination. When the habit is once broken, the return to health is rapid and sure, and an otherwise healthy patient is able to resume his ordinary vocation. The after-treatment with a great many consists of attention to the bowels, good nourishing food, moderate exercise and plenty of sleep. Do not give alcoholic stimulants, for the administration of stimulants is always followed by a depression, which gives rise to a desire for another dose of the stimulant.

118 *Simple and Safe Method for Performance of Partial Thyroidectomy. L. Freeman, Denver, Colo.

118. **Partial Thyroidectomy.**—In Freeman's method the gland is exposed through an ordinary collar incision, and the lobe to be removed is dislocated. In the average case there is but little hemorrhage or risk of any kind. Two pieces of wire are then cut, some inches longer than the length of the thyroid. Several loops (usually three) of strong, heavy catgut are next passed directly through the lobe, near the base, from one side to the other—one near each end, and one or more between these, according to the size of the gland. The loops are most conveniently inserted by plunging alligator forceps through the thyroid substance and grasping a strand of gut by its center; although a blunt needle, threaded with both ends of the loop, may be employed instead. A wire is then placed longitudinally along each side of the base of the lobe, passing through the loops on one side and between their free ends on the other. These are held at each end by the fingers of an assistant, thus firmly compressing the glandular substance while the free ends of the loops are being tied firmly over their corresponding wire. Additional

security may be obtained at each extremity by taking a turn around the projecting portions of the wires with the remaining ends of the loops after the first knots are tied. In some cases, especially when the goiter is a large one, the loops may be made double, thus increasing their holding power. When the wires are once in position they cannot slip or become displaced in any way because they are securely held by the catgut loops passing through both glandular substance and capsule. Their pressure is great enough, when properly applied, to check the circulation, so that the gland may be shaved off beyond them like a piece of cheese, without the slightest hemorrhage and with a satisfying sense of security. A small margin should be left, as a support for the wires and sutures.

The glandular stump is now replaced in its original position by the side of the trachea, the upward projecting ends of the wires being previously removed with wire-cutters. When necessary, the long ends of the wires, projecting downwards, are then bent forwards by means of pliers, in order that they may pass easily through the wound and over the upper end of the sternum without pressure on the skin. The various tissues are now united over the thyroid stump; the ends of the wires passing through the center of the skin wound, between the stitches and down over the sternum. They must be long enough to prevent the possibility of slipping beneath the skin, and, as a further precaution, their ends can be bent into a loop, through which a small strip of gauze may be pulled.

In applying the dressings a layer of gauze is placed beneath the wires in order to protect the skin. Other drainage than that afforded by the wires is unnecessary.

In a few days the wires become loosened, through absorption of the catgut and shrinkage of the compressed tissues, when they can easily be pulled out, the small opening through which they emerged soon closing spontaneously. They produce no particular discomfort, the patient being able to get up and walk about as freely as if ordinary drainage tubes had been employed.

The advantages of the method are said to be: (1) It is easily and quickly done. (2) The control of hemorrhage is complete. (3) There is no danger of injuring the recurrent laryngeal nerves or the parathyroid bodies. (4) There is reason to think that the uniform pressure may prevent the exudation of glandular secretion, a point of some importance in exophthalmic goiter. (5) Any desired amount of glandular substance can be excised from one or both sides, without danger of removing or leaving too much. (6) The wires do not crush the tissues—they simply compress them enough to control hemorrhage and stop the exudation of glandular secretion.

2. **Cancer.**—This paper is an analysis of the conditions under which the new cell characters which we associate with cancer arise in somatic cells; to inquire whether the three conditions which accompany variation and selection among other organisms are also concerned in the evolution of cancer. These are: (1) struggle for existence among cells; (2) cell proliferation; and (3) cell destruction. Bond describes blastomatosis as an adaptive response on the part of individual cells, or cell groups, to environmental change of three kinds: alteration in the stimuli which reach the cell from the outside world; alteration in nutrition; alteration in the activities of the other cells which compose the organism. This adaptive response may be "indirect," the result of variation among the cells exposed to the changed conditions, accompanied by selection of an intercellular kind, or it may be "direct," and the result of a process of variation in the physiologically differentiated parts which compose the individual cell, accompanied by selection of an intracellular kind, in which case it represents a "use acquirement." The new cell characters which so arise may be grouped in two main divisions—one characterized by typical growth, including all the histologic varieties of benign neoplasms from teratoma to neuroma, the other characterized by atypical growth including the malignant types. But between these two groups there are numerous tumors composed of cells presenting transitional characters. Yet, again, the second group, characterized by atypical growth, may be divided into neoplasms composed of cells of epithelial type, and neoplasms composed of cells of connective-tissue type. And between these two groups there are again connecting links, for the malignant tumors which arise from cells of primary mesoblastic and secondary epithelial origin tend to exhibit transitional characters.

Of the two factors concerned in the origin of malignant growth (cell potentiality and environmental influence), environmental influence plays a large part in the genesis of cancer, cell potentiality in the genesis of sarcoma. Of the environmental factors concerned, outside stimuli exert a much larger influence in the genesis of epithelial than of connective-tissue cancer. Bond believes that a comparison of this theory with others at present held shows that cancer, like all "new growth," must be regarded in the light of a response of an adaptive kind on the part of certain cells or cell-groups of varying potentiality, to changes in their environment. It suggests that in epithelial cancer, at any rate, this response takes place under the same conditions as those which are associated with the occurrence of variation and selection among other organisms when exposed to environmental change and where evolution of new characters is taking place, especially in response to changes in the external environment. And the suggestion is therefore made that blastomatosis, including cancer and certain other forms of cell multiplication, takes place under the influence of the same evolutionary factors, namely, variation and selection of the "inter-" or "intra-" cellular kind.

4. **Toxemia of Uncertain Origin.**—The symptoms in this case pointed to some inflammatory infection and possibly ulceration of the bowel, chiefly in the region of the cecum and ascending colon. There were some enlargement and tenderness of the liver. Drugs and vaccine-therapy failed utterly to give relief. Finding that in spite of all treatment the patient was losing ground rapidly, the sea-water injection was given, beginning with 25 c.c. of sea-water (plasma marina), injected und

similar milder attacks which "blew over." The discovery of gall-stones, however, possibly accounted for the previous disturbances. One patient said he had had occasional gall-stone colics but no evidences of cholelithiasis were found at necropsy. The sudden intense pain was sometimes accompanied by vomiting and retching but the most characteristic feature is the shock-like, systemic depression while the abdominal findings do not suggest peritonitis of such severity as to account for it. The heart and kidney functioning suffer intensely and death may occur within a few hours or at once.

50. **Gastric Endothelioma.**—Jørgensen reports a case of successful resection of half of the stomach on account of an endothelioma in a woman of 58. The first symptoms had been noted two or three months before, an occasional sensation of oppression in the epigastrium, but with no connection with the meals, no eructation, vomiting or hemorrhage, but for a year there had been a few days of diarrhea every two or four weeks, and she consulted a physician on account of the intestinal trouble. He found a palpable tumor and she gained several pounds at once after the operation and had been in perfect health during the thirteen months since. Jørgensen states that he has been able to find only four certain cases of gastric endothelioma on record. The description of the microscopic findings in Maylard's and Anderson's case (1910) does not justify the assumption of endothelioma according to his opinion, and neither do the four cases published by Fick, Cignozzi, Aldegarman and Meinel. The only ones he accepts are those of Jungmann, Hansemann, Ssobolew and Donath, one in a woman of 28. Although the tumors were small yet there was extensive metastasis in this and in Donath's case. In one of these and in Jørgensen's own case the tumor was a solitary round growth, in another it was multiple and in Donath's case a flat cake, more like an adenocarcinoma.

51. **Coasting and Snow-Shoe Accidents.**—Saar describes the mechanism and aspect of the various fractures liable in these sports, and says that they throw light on fractures in general, as he explains in detail.

59. **Wall Endocarditis.**—Bäumler gives an analytic study of the four cases of this kind which he has encountered and compares them with similar ones on record. Among the various forms which strips of induration (*Schwielen*) in the endocardium and myocardium may assume, the form known as chronic wall endocarditis occurs almost exclusively in the left ventricle and it may develop without any trouble in the valves. Although the changes in the wall may be severe, yet the pulse may persist quite normal for years and the whole affection run a latent course. An acute commencement may be surmised but seldom can be proved. The principal manifestation of wall endocarditis is the dilatation of the left ventricle and development of a heart aneurysm, located mainly in the apex region. Extensive arteriosclerosis and chronic nephritis may be entirely lacking although they are otherwise so frequent with indurations in the heart. When compensation begins to fail, symptoms of cardiac insufficiency may be observed (dyspnea, cardiac asthma, stasis, relative mitral insufficiency, hydrops and albuminuria). But these symptoms can be made to disappear again and again under appropriate treatment. The deterioration of the left ventricle may be manifested—even without signs of cardiac insufficiency or after they have disappeared—by the attenuation of the first sound at the apex and by considerable weakening or total absence of the apex beat. Thrombi may develop in the spaces between the trabeculæ even without the development of an actual aneurysm. It sometimes happens also that thrombi may form in the right heart, owing to the insufficiency of the left ventricle or under the influence of some infection, and infarcts may develop from embolism in the lungs. According to the site and progress of the indurations the conducting system may become impaired. In a number of such cases the pulse became very slow but there was no lasting irregularity of the pulse-rate in Bäumler's cases and in a number of others on record of myocardium indurations. The prognosis becomes unfavorable when symptoms of cardiac insufficiency begin to manifest themselves. In quite a number of such cases in the literature sudden death occurred, sometimes without any preceding symptoms on the part of the heart.

63. **Treatment of Obesity by Restriction to Milk.**—Jacob reports eight additional cases of obesity in which the metabolic findings are tabulated during a course of exclusively milk diet at Moritz' medical clinic at Strasburg. These findings and the experiences with a large number of others all confirm the advantages of the strict milk diet in treatment of obesity in many cases. The simplicity of the method, its prompt efficacy while the patients have their appetite appeased and feel well, although the diet is so far below their normal needs—all these factors cooperate in the advantages of this method of reducing obesity. No by-effects or inconveniences have been observed with it. The deficit of protein does not seem to do any harm to the patients under the circumstances.

66. **Determination of Proportion of Epinephrin in the Blood.**—Bröking and Trendelenburg present evidence to show that epinephrin is present in normal blood in a proportion of about 1 to 2,500,000 and that this proportion is doubled and quadrupled in true exophthalmic goiter. In arteriosclerosis, in pregnant women and parturients the proportion persists normal while in chronic nephritis with arterial hypertension it is a little subnormal. They have devised a method for estimating the proportion in the blood which, they state, has proved constantly reliable. The principle of the new method of examination is to pass the blood through the vascular system of the frog kept functioning with Ringer's solution. The frog reacts with a vasoconstriction to epinephrin, and its presence is thus determined. The Ringer's solution is forced into the abdominal aorta of the frog whence it passes through the femoral arteries in the legs and out again through the femoral veins into the abdominal vein whence it passes into a glass cannula inserted in this vein, from which the fluid drips in a constant tempo. The drops automatically record themselves on a reviving drum. A curve of the drops is given showing how when epinephrin or blood containing epinephrin is added to the solution being forced into the abdominal aorta, vasoconstriction at once follows and it is plainly shown by the longer intervals between the drops as registered on the drum. This frog-flushing method has the advantage over other technics that it works physiologically; the epinephrin acts on the nerve terminals of the muscle cells in the vessels—its normal mode of action. The test is so sensitive, at least during the summer, that it reveals even minute proportions of epinephrin, while the same specimen of serum can be used over and over again even when it has commenced to putrefy. The vasoconstriction reaction seems to be specific for epinephrin; *none* of the numerous other substances tested give this vasoconstriction reaction in the same way and *none except in a* hundred or thousand-fold concentration, and the vasoconstriction is not so intense and does not subside so promptly.

18. **Abdomino-Pelvic Pain in Women.**—In the treatment of cases of pelvic pain without physical signs Bonney says one should begin with purgatives, for many women go about with an habitually overloaded colon although the bowels are open every day. Ordinary "white mixture" three times a day is as good as anything. Later, when it is assured that the colon is well emptied, the following prescription is used instead:

℞.	gm. or c.c.			
Extracti cascaræ sagradæ..........	4			ʒi
Magnesii sulphatis	4		or	ʒi
Tincturæ hyoscyami	2			ʒss
Aquam menthæ piperitæ.........ad	30			℥i

One to two tablespoonfuls at night as required.

When flatulence is believed to play some part in the trouble he has found either of the two following very serviceable:

℞.	gm. or c.c.			
Potassii bicarbonatis		60		gr. x
Tincturæ zingiberis		60		m x
Spiritus chloroformi		60	or	m x
Infusi rhei	2			m xxx
Infusi gentianæ	30			℥i

Sig.: T. d. s.

and

℞.	gm. or c.c.			
Extracti aloes		060		gr. i
Essentiæ menthæ piperitæ..........		20		m iii
Tincturæ capsici		30		mv
Aquam ....ad	30			℥i

Sig.: T. d. s.

The following prescription Bonney finds excellent, especially if gastric symptoms are present as well:

℞.	gm. or c.c.			
Bismuthi salicylatis		60		gr. x
Sodii salicylatis		60		gr. x
Spiritus chloroformi	1		or	m xv
Aquam menthæ piperitæ..........ad	30			℥i

Three times a day.

In cases with evident neurosis sedative drugs are indicated, the bromids in particular. He looks on the following mixture as the most useful in cases of abdomino-pelvic pain without physical signs:

℞.	gm. or c.c.			
Potassii bromidi	1	30		gr. xx
Spiritus chloroformi		60	or	m x
Infusii cinchonæ	30			℥i

Sig.: T. d. s.

A great number of these patients are out of health generally quite apart from their local complaints. To such the administration of ferruginous tonics containing strychnin is always beneficial. Bonney finds that the best results are obtained with the milder preparations of iron such as the ammoniated citrate, because the digestion is usually too disordered to tolerate the more astringent forms. A favorite prescription of his is:

℞.	gm. or c. c.			
Ferri ammoniæ citratis............		60		gr. x
Liquoris strychninæ		30		m v
Spiritus chloroformi		30	or	m v
Aqua ....ad	30			℥i

Sig.: T. d. s.

20. **Puerperal Septic Thrombo-Phlebitis.**—Bell is fully persuaded that when every patient with septic thrombo-phlebitis of the pelvic veins is operated on in the early stages the mortality will drop to, say, 5 per cent. as against the 60 per cent. of those treated by expectant methods.

24. **Esophagismus.**—Tibbetts' patient was 59 years old; complained of pains in the knees and shoulders; had an urticarial rash scattered over the body, especially abundant on the face, arms and chest, and also complained of a cough, which, as the chest signs were normal and the fauces rather injected, Tibbetts attributed to pharyngeal catarrh. The temperature was 100 F., and the urine was normal. The patient was kept in bed and a milk diet and salicylates were prescribed. For the next three days there was no material change. On the night of the third day the patient was in great distress. His aspect was that of the gravest anxiety. Every few seconds there were retching efforts almost amounting to convulsions, and from his mouth saliva poured profusely. By gestures and broken speeches he intimated that under the lower part of the sternum there was severe pain, and that he thought he should be suffocated. All attempts to swallow provoked fresh paroxysms. Fifteen years before he had had a similar, but much milder, attack, and from this fact, as well as from the absence of abnormal physical signs at the previous examination and its association with rash and pharyngitis, Tibbetts ventured a favorable prognosis. Poultices were applied to the chest, steam inhalations administered, and a mixture of bismuth and soda prescribed. The saliva and dysphagia continued for five or six hours, both subsiding gradually and simultaneously, and until then the patient had been unable to swallow either milk or medicine.

Next evening all the symptoms returned, and they continued to remit and recur at irregular intervals of from six to twelve hours' duration. So severe were the attacks that the eyelids became suffused and the eyes ecchymosed to the extent that one sees in bad cases of whooping cough, or in prolonged parturition, and in a single attack the saliva lost amounted to ½ pint or more. For the pain during the second and succeeding attacks Tibbetts gave a hypodermic injection of morphin (gr. ¼). This always relieved the symptoms, and sleep usually resulted, lasting for two or three hours. Except at first, the temperature was normal throughout, but the pulse became progressively feebler and more rapid. Such drugs as might be expected to influence the attacks were tried, but, excepting as influenced by the morphin, the attacks of pain, the salivation, and the dysphagia persisted unchecked for over a fortnight. The rash was practically constant throughout. At the end of a fortnight Tibbetts first tried a hypodermic injection of atropin (1/100 gr.), with a view to reducing the ptyalism which had been so marked a feature during each attack. In a few minutes salivation and spasm abated, and in an hour or so the patient was able to take liquid food easily. The injection was repeated in four hours' time and atropin in small doses (liq. atropin, mj.) was further administered orally at intervals of four hours. In less than twenty-four hours the rash had vanished, soon the patient's convalescence became assured, and a month later he resumed his ordinary occupation in which he has been able to continue.

39. **Roentography with Kidney Calculi.**—Arcelin states that instantaneous exposures are liable to show up the stones much better than longer ones unless the kidney is completely

strict aseptic precaution, in the right scapular region. As it was followed by no discomfort, it was subsequently increased from 25 to 50 c.c., and continued twice weekly for thirty injections. The temperature soon began to fall to normal, but at first after each injection it would fall and then rise again to 100 or therabouts before the next injection was given. This continued for a time until it came down and remained at normal. The patient began to increase in weight. Sleep became natural. although up to that time it had to be induced by hypodermic injections of morphin. The improvement continued, the stools became formed and regular, appetite gradually improved, and she thoroughly enjoyed her meals, and a more liberal diet was given. The apical murmur, previously present, disappeared, as did also the anemic condition. At the end of six weeks she was for the first time able to leave her bed and sit up daily in a chair. Each week she gained on an average a little over half a pound in weight. After each injection she described herself as feeling much stronger, and they seemed to act as a powerful tonic to her general system. Finally, six months after the beginning of the sea-water treatment, she was able to take outdoor exercise and live her ordinary life.

17. **Celiac Disease.**—Celiac disease is defined by Hutchison as a chronic wasting disease of childhood characterized by chronic diarrhea with large, pale and offensive stools, running a prolonged course with a great tendency to relapses, exhibiting often certain nervous complications, such as weakness of the legs and tetany, and ending either in death or in complete recovery, or in partial recovery with great impairment of growth and development (similar to or identical with the infantilism of Herter). The cause of the disease is obscure. Social surroundings seem to play little if any part in the etiology. Any acute attack of enteritis, whether from infection, poisoning, irritation of undigested food, or exposure to cold, seems able to serve as a starting point of the disease. The disease usually begins insidiously in the second or third year of life. The child is observed to be pale, listless and fretful, and to be losing flesh and strength. If inquiry is made into the state of the stools they will be found to be increased in number, usually about two or three in the twenty-four hours, and still more increased in bulk. They are usually of the consistence of porridge, pale or even quite white in color, and of an extremely offensive odor. Sometimes they contain streaks of visible mucus or blood, and undigested food particles can often be observed in them. The appetite is poor or capricious, and there is often considerable thirst. Physical examination reveals some degree of anemia; with wasting of the subcutaneous tissues and flabbiness of the muscles. The abdomen is distended and tympanitic. The temperature is often slightly elevated at night.

As the disease progresses certain nervous symptoms may become manifest. Chief of these is weakness of the lower extremities, which may be accompanied by loss of the knee-jerks. Attacks of tetany are not uncommon, and there may even be epileptiform convulsions. Edema, especially of the extremities, may occur without any evidence of renal disease, just as it does in other forms of chronic gastro-intestinal disorder in childhood. The mental condition is apt to be peculiar, there being often a high degree of precocity along with a tendency for the child to be unduly interested in his own symptoms, which is most unusual at this age. Sometimes, indeed, they are actual little hypochondriacs, and almost always they are spoilt.

If one makes a post-mortem examination of a fatal case of this disease, nothing at all is found by inspection except some atrophy of the intestinal wall. The condition most apt to simulate celiac disease is abdominal tuberculosis, and it is often extremely difficult to distinguish between them. In celiac disease, however, there are no enlarged glands to be felt and no thickened and rolled-up omentum, nor is there any ascites. A negative Pirquet's test is also of value in the diagnosis. The distinction is rendered still more difficult by reason of the fact that abdominal tuberculosis seems sometimes to supervene on the celiac disease after the latter has lasted some time. The course of the disease is an extremely chronic one, the duration extending to years with intervals of improvement, followed by the most disheartening relapses, which may take place in spite of every care. Complete and permanent recovery, however, may certainly occur. It took place in at least seven out of the sixteen cases which have been under Hutchison's observation, in some of which the disease had lasted for two or even three years. If a fatal result ensues it is usually the consequence of some intercurrent disease, such as bronchopneumonia. When the disease has lasted some time it leads to a retardation of growth, which may leave the child frail and stunted even when the intestinal symptoms have disappeared. In well-marked cases the interference with growth may amount to a condition of true infantilism, such as Herter described. Of this Hutchison has seen two pronounced examples, both of which were fatal. The way in which the arrest of development is brought about has already been discussed.

In the treatment of celiac disease a suitable diet is of the first importance. Owing to the impaired absorption of fats, the amount of fatty food must be greatly curtailed, and as starches are also badly borne these, too, must be avoided. and the diet should consist of raw or underdone meat, raw meat juice and skim-milk (preferably peptonized), gelatin in the form of jellies of different sorts and dextrinized foods. The raw meat and meat juice should form the basis of the dietary, and a child of 4 years may take as much as 6 ounces of the former and 10 of the latter daily. As improvement sets in, a little stale white bread and boiled rice may be added to the diet, as these contain starch in a form in which it is most easily borne. Under this regimen the stools usually decrease in number and amount and improve in color, while abdominal distention is lessened. In the general hygienic treatment great care should be taken to avoid chill. A warm binder should be worn over the abdomen, and the legs, which are very apt to be cold, should be warmly covered; it is sometimes even necessary to wrap them in cotton-wool and bandages. Special precautions should also be taken to avoid chill in bathing the child. Change of air to a bracing sea-side place is of great help, especially when the appetite is defective, and will often start an improvement when the case is "hanging fire." Medicinal treatment is of secondary importance, but opium is always useful. It may be given in doses of 1 minim of the tincture for every year of the child's age, along with bitters and carminatives. It tends greatly to lessen the offensiveness of the stools. If diarrhea be severe nitrate of silver is the most potent astringent. It may be given in doses of 1/6 grain with 1 or 2 drops of dilute nitric acid in a little glycerin and distilled water three times daily, and may be continued for weeks if necessary. Active preparations of pancreas are also of value, especially when the stools contain much unaltered fat.

18. **Abdomino-Pelvic Pain in Women.**—In the treatment of cases of pelvic pain without physical signs Bonney says one should begin with purgatives; for many women go about with an habitually overloaded colon although the bowels are open every day. Ordinary "white mixture" three times a day is as good as anything. Later, when it is assured that the colon is well emptied, the following prescription is used instead:

℞.	gm. or c.c.		
Extracti casearæ sagradæ	4		ʒi
Magnesii sulphatis	4	or	ʒi
Tincturæ hyoscyami	2		ʒss
Aquam menthæ piperitæ ad	30		℥i

One to two tablespoonfuls at night as required.

When flatulence is believed to play some part in the trouble he has found either of the two following very serviceable:

℞.	gm. or c.c.		
Potassii bicarbonatis	60		gr. x
Tincturæ zingiberis	60		m x
Spiritus chloroformi	60	or	m x

In well-marked cases the interference with growth may amount to a condition of true infantilism, such as Herter described. Of this Hutchison has seen two pronounced examples, both of which were fatal. The way in which the arrest of development is brought about has already been discussed.

In the treatment of celiac disease a suitable diet is of the first importance. Owing to the impaired absorption of fats, the amount of fatty food must be greatly curtailed, and as starches are also badly borne these, too, must be avoided, and the diet should consist of raw or underdone meat, raw meat juice and skim-milk (preferably peptonized), gelatin in the form of jellies of different sorts and dextrinized foods. The raw meat and meat juice should form the basis of the dietary, and a child of 4 years may take as much as 6 ounces of the former and 10 of the latter daily. As improvement sets in, a little stale white bread and boiled rice may be added to the diet, as these contain starch in a form in which it is most easily borne. Under this regimen the stools usually decrease in number and amount and improve in color, while abdominal distention is lessened. In the general hygienic treatment great care should be taken to avoid chill. A warm binder should be worn over the abdomen, and the legs, which are very apt to be cold, should be warmly covered; it is sometimes even necessary to wrap them in cotton-wool and bandages. Special precautions should also be taken to avoid chill in bathing the child. Change of air to a bracing sea-side place is of great help, especially when the appetite is defective, and will often start an improvement when the case is "hanging fire." Medicinal treatment is of secondary importance, but opium is always useful. It may be given in doses of 1 minim of the tincture for every year of the child's age, along with bitters and carminatives. It tends greatly to lessen the offensiveness of the stools. If diarrhea be severe nitrate of silver is the most potent astringent. It may be given in doses of 1/6 grain with 1 or 2 drops of dilute nitric acid in a little glycerin and distilled water three times daily, and may be continued for weeks if necessary. Active preparations of pancreas are also of value, especially when the stools contain much unaltered fat.

18. **Abdomino-Pelvic Pain in Women.**—In the treatment of cases of pelvic pain without physical signs Bonney says one should begin with purgatives, for many women go about with an habitually overloaded colon although the bowels are open every day. Ordinary "white mixture" three times a day is as good as anything. Later, when it is assured that the colon is well emptied, the following prescription is used instead:

℞.	gm. or c.c.			
Extracti cascaræ sagradæ	4			ʒi
Magnesii sulphatis	4		or	ʒi
Tincturæ hyoscyami	2			ʒss
Aquam menthæ piperitæ ... ad	30			℥i

One to two tablespoonfuls at night as required.

When flatulence is believed to play some part in the trouble he has found either of the two following very serviceable:

℞.	gm. or c.c.			
Potassii bicarbonatis		60		gr. x
Tincturæ zingiberis		60		m x
Spiritus chloroformi		60	or	m x
Infusi rhei	2			m xxx
Infusi gentianæ	30			℥i

Sig.: T. d. s.

and

℞.	gm. or c.c.			
Extracti aloes		060		gr. i
Essentiæ menthæ piperitæ		20		m iii
Tincturæ capsici		30		m v
Aquam ... ad	30			℥i

Sig.: T. d. s.

The following prescription Bonney finds excellent, especially if gastric symptoms are present as well:

℞.	gm. or c.c.			
Bismuthi salicylatis		60		gr. x
Sodii salicylatis		60		gr. x
Spiritus chloroformi	1		or	m xv
Aquam menthæ piperitæ ... ad	30			℥i

Three times a day.

In cases with *evident neurosis* sedative drugs are *indicated*, the bromids in particular. He looks on the following mixture as the most useful in cases of abdomino-pelvic pain without physical signs:

℞.	gm. or c.c.			
Potassii bromidi	1	30		gr. xx
Spiritus chloroformi		60	or	m x
Infusii cinchonæ	30			℥i

Sig.: T. d. s.

A great number of these patients are out of health generally quite apart from their local complaints. To such the administration of ferruginous tonics containing strychnin is always beneficial. Bonney finds that the best results are obtained with the milder preparations of iron such as the ammoniated citrate, because the digestion is usually too disordered to tolerate the more astringent forms. A favorite prescription of his is:

℞.	gm. or c. c.			
Ferri ammoniæ citratis		60		gr. x
Liquoris strychninæ		30		m v
Spiritus chloroformi		30	or	m v
Aqua ... ad	30			℥i

Sig.: T. d. s.

20. **Puerperal Septic Thrombo-Phlebitis.**—Bell is fully persuaded that when every patient with septic thrombo-phlebitis of the pelvic veins is operated on in the early stages the mortality will drop to, say, 5 per cent. as against the 60 per cent. of those treated by expectant methods.

24. **Esophagismus.**—Tibbetts' patient was 59 years old; complained of pains in the knees and shoulders; had an urticarial rash scattered over the body, especially abundant on the face, arms and chest, and also complained of a cough, which, as the chest signs were normal and the fauces rather injected, Tibbetts attributed to pharyngeal catarrh. The temperature was 100 F., and the urine was normal. The patient was kept in bed and a milk diet and salicylates were prescribed. For the next three days there was no material change. On the night of the third day the patient was in great distress. His aspect was that of the gravest anxiety. Every few seconds there were retching efforts almost amounting to convulsions, and from his mouth saliva poured profusely. By gestures and broken speeches he intimated that under the lower part of the sternum there was severe pain, and that he thought he should be suffocated. All attempts to swallow provoked fresh paroxysms. Fifteen years before he had had a similar, but much milder, attack, and from this fact, as well as from the absence of abnormal physical signs at the previous examination and its association with rash and pharyngitis, Tibbetts ventured a favorable prognosis. Poultices were applied to the chest, *steam inhalations administered, and a mixture of bismuth* and soda prescribed. The saliva and dysphagia continued for five or six hours, both subsiding gradually and simultaneously, and until then the patient had been unable to swallow either milk or medicine.

Next evening all the symptoms returned, and they continued to remit and recur at irregular intervals of from six to twelve hours' duration. So severe were the attacks that the eyelids became suffused and the eyes ecchymosed to the extent that one sees in bad cases of whooping cough, or in prolonged parturition, and in a single attack the saliva lost amounted to ½ pint or more. For the pain during the second and succeeding attacks Tibbetts *gave a hypodermic injection of morphin* (gr. ¼). This always relieved the symptoms, and sleep usually resulted, lasting for two or three hours. Except at first, the temperature was normal throughout, but the pulse became progressively feebler and more rapid. Such drugs as might be expected to influence the attacks were tried, but, excepting as influenced by the morphin, the attacks of pain, the salivation, and the dysphagia persisted unchecked for over a fortnight. The rash was practically constant throughout. At the end of a fortnight Tibbetts first tried a hypodermic injection of atropin (1/100 gr.), with a view to reducing the ptyalism which had been so marked a feature during each attack. *In a few minutes salivation and spasm abated, and* in an hour or so the patient was able to take liquid food easily. The injection was repeated in four hours' time and atropin in small doses (liq. atropin, mj.) was further administered orally at intervals of four hours. In less than twenty-four hours the rash had vanished, soon the patient's convalescence became assured, and a month later he resumed his ordinary occupation in which he has been able to continue.

38. **Appendicitis and Traumatism.**—Bérard and Vignard study the clinical and medicolegal aspects of appendicitis following or aggravated by traumatism, thus analyzing twenty-nine cases, the majority previously unpublished.

39. **Roentography with Kidney Calculi.**—Arcelin states that instantaneous exposures are liable to show up the stones much better than longer ones unless the kidney is completely

immobilized. He insists further that the roentgenographer should always be present at the operation so that he can identify the stones by *their shadows* and see that none is overlooked. Arcelin gives twenty-six different views of kidney stones to show the various sources of error.

40. **Volvulus of the Testicle.**—The patient was a young man and the *true nature of the trouble* was not recognized at first, treatment being applied on the diagnosis of acute orchitis. He had had mumps in youth and acute articular rheumatism but there was no history of venereal disease. The first sign of *trouble had been a* sudden intense pain, with syncope, progressive swelling and tenderness in the region, but there was nothing to indicate general infection. The condition at last compelled an operation which revealed that the spermatic cord had twisted entirely around inside the vaginalis. The torsion was readily reduced but the disturbance in the circulation had been of such long standing that conservative measures were no longer possible.

47 Snapping Hip Joint. (La hanche à ressort.) L. Heully. Commenced in No. 5.

43. **Relations of the Corpus Luteum and the Mammary Gland.**—Brouin and Ancel sum up their studies of the relations of the corpus luteum and the mammary gland with the statement that the corpus luteum is a gland of internal secretion which governs the development of the mammary gland both during pregnancy and in its absence. In mammals which have no spontaneous ovulation there is normally no corpus luteum except during pregnancy, and the mammary gland develops only during that period. In women and in other mammals with spontaneous ovulation, on the other hand, alternate enlargement and diminution of the mammæ are observed which correspond with the intergestational development of corpora lutea. These mammary crises manifest themselves from the beginning of puberty to the end of sexual life, in the course of the menstrual period in woman and during the heat in animals.

The mammary gland is, therefore, an organ under the influence of the corpus luteum outside of pregnancy and during the first half of gestation. The corpus luteum stimulates growth of the organ, but cannot induce secretion. The latter function is probably due to a hormone introduced into the maternal blood during the latter part of pregnancy. The authors advance the hypothesis that this hormone is the product of a gland which they have discovered in the uterine muscle and to which they give the name "myometrial gland."

44. **Woody Thyroiditis.**—Delore and Alamartine report a case of transformation of the thyroid gland into a hard mass causing serious symptoms from compression. On suspicion of cancer half of the gland was removed but the microscope revealed the woody texture of the thyroid and adjacent tissues which Riedel has described as chronic ligneous strumitis. Their patient succumbed to a fulminating hemorrhage six hours after changing the dressing, four days after the operation. They review thirteen cases on record, including six from Riedel's experience. In only one of the cases was tuberculosis evident, but Leriche and Cotte recently reported a case in which the ligneous thyroiditis was of syphilitic origin and subsided under mercury and iodid. Silatschek and Barjon have each reported a case in which a cure was realized under a course of Roentgen-ray treatment, and this should be advocated in the forms without menacing functional disturbance. This affection should be suspected when the thyroid swells rapidly and becomes extremely hard, early interfering with respiration. The patients are usually between 30 and 40. As it is a purely inflammatory affection, medical measures or partial operations prove effectual, without recurrence. Tracheotomy is useless or difficult; the best operative technic is by resection of a wedge from the isthmus to liberate the trachea.

46. **Postoperative Intoxication in Echinococcus Disease.**—Dévé's attention was called to this subject by the sudden death nineteen hours after operation for a hydatid cyst in the liver in a child of 5½. The urine contained no formaldehyd and this, with the results of extensive experimental research, excluded the possibility of intoxication from the small amount of antiseptic injected. He has found on record twelve cases of mild intoxication after puncture of an echinococcus cyst and fifteen cases of severe symptoms of the kind, with twelve fatal cases and three in which the patients died soon after puncture of a hydatid cyst in the lung. He reviews also thirty-six cases of mild postoperative intoxication of the kind and twenty fatal cases. Study of this material and of the symptoms presented have convinced him that the whole trouble is a manifestation of anaphylaxis. The echinococcus poison may have dialyzed through the walls of the cyst, sensitizing the patient, or this result may have been accomplished by a preceding puncture. As he reviews the symptoms, the analogy with the symptoms of anaphylaxis in experiments on animals and in veterinary practice is striking. In prophylaxis every effort must be made to prevent the escape of the toxic fluid from the cyst into the surrounding tissues—even a minute quantity is liable to set up the anaphylaxis. It may prove possible to immunize the patient before operating, by some preventive anti-anaphylactic treatment, such as Besredka has realized in animals by repeated injection of small amounts of the serum. Certain biologists maintain that anaphylaxis is not strictly specific; if so, general anti-anaphylactic measures might prove effectual. Some have suggested general anesthesia in treatment of anaphylaxis, but Marion's case may be regarded as a failure of chloroform in this respect; possibly general anesthesia with ethyl chlorid or ether might answer better. This treatment seems to be justified in the nervous form of hydatid intoxication with convulsions, whose prognosis is almost inevitably fatal. Chloral might be indicated in such cases.

56 Outcome of Gastroenterostomies for Gastric Ulcer. P. A. Albrecht.

49. **Acute Disease of the Pancreas.**—Borelius reports a case of acute pancreatitis and eleven of hemorrhage in the pancreas; the trouble in the latter was probably not of infectious origin. In the first case the acute suppurative pancreatitis was evidently secondary to the gall-bladder. A gall-stone had become impacted at the papilla of Vater and the pancreatic duct was full of pus; but there were no signs of fat necrosis. No operation was attempted; the case dates from 1899. Only four recovered of the eleven patients with hemorrhage in the pancreas. The ages ranged from 29 to 74; three were obese and five very stout and one was quite thin. Cholelithiasis was evident in three and arteriosclerosis in two. There was a history of trauma in only one case, and a cyst was found in the pancreas in another. Six of the patients belonged to the well-to-do classes and the others were bank messengers or coachmen. Alcoholism was manifest in two cases and four other patients were "high livers." The trouble generally came on suddenly with violent pain, like a perforation peritonitis, but some of the patients said that they had previously had

similar milder attacks which "blew over." The discovery of gall-stones, however, possibly accounted for the previous disturbances. One patient said he had had occasional gall-stone colics but no evidences of cholelithiasis were found at necropsy. The sudden intense pain was sometimes accompanied by vomiting and retching but the most characteristic feature is the shock-like, systemic depression while the abdominal findings do not suggest peritonitis of such severity as to account for it. The heart and kidney functioning suffer intensely and death may occur within a few hours or at once.

50. **Gastric Endothelioma.**—Jørgensen reports a case of successful resection of half of the stomach on account of an endothelioma in a woman of 58. The first symptoms had been noted two or three months before, an occasional sensation of oppression in the epigastrium, but with no connection with the meals, no eructation, vomiting or hemorrhage, but for a year there had been a few days of diarrhea every two or four weeks, and she consulted a physician on account of the intestinal trouble. He found a palpable tumor and she gained several pounds at once after the operation and had been in perfect health during the thirteen months since. Jørgensen states that he has been able to find only four certain cases of gastric endothelioma on record. The description of the microscopic findings in Maylard's and Anderson's case (1910) does not justify the assumption of endothelioma according to his opinion, and neither do the four cases published by Fick, Cignozzi, Aldegarman and Meinel. The only ones he accepts are those of Jungmann, Hansemann, Ssobolew and Donath, one in a woman of 28. Although the tumors were small yet there was extensive metastasis in this and in Donath's case. In one of these and in Jørgensen's own case the tumor was a solitary round growth, in another it was multiple and in Donath's case a flat cake, more like an adenocarcinoma.

51. **Coasting and Snow-Shoe Accidents.**—Saar describes the mechanism and aspect of the various fractures liable in these sports, and says that they throw light on fractures in general, as he explains in detail.

59. **Wall Endocarditis.**—Bäumler gives an analytic study of the four cases of this kind which he has encountered and compares them with similar ones on record. Among the various forms which strips of induration (*Schwielen*) in the endocardium and myocardium may assume, the form known as chronic wall endocarditis occurs almost exclusively in the left ventricle and it may develop without any trouble in the valves. Although the changes in the wall may be severe, yet the pulse may persist quite normal for years and the whole affection run a latent course. An acute commencement may be surmised but seldom can be proved. The principal manifestation of wall endocarditis is the dilatation of the left ventricle and development of a heart aneurysm, located mainly in the apex region. Extensive arteriosclerosis and chronic nephritis may be entirely lacking although they are otherwise so frequent with indurations in the heart. When compensation begins to fail, symptoms of cardiac insufficiency may be observed (dyspnea, cardiac asthma, stasis, relative mitral insufficiency, hydrops and albuminuria). But these symptoms can be made to disappear again and again under appropriate treatment. The deterioration of the left ventricle may be manifested—even without signs of cardiac insufficiency or after they have disappeared—by the attenuation of the first sound at the apex and by considerable weakening or total absence of the apex beat. Thrombi may develop in the spaces between the trabeculæ even without the development of an actual aneurysm. It sometimes happens also that thrombi may form in the right heart, owing to the insufficiency of the left ventricle or under the influence of some infection, and infarcts may develop from embolism in the lungs. According to the site and progress of the indurations the conducting system may become impaired. In a number of such cases the pulse became very slow but there was no lasting irregularity of the pulse-rate in Bäumler's cases and in a number of others on record of myocardium indurations. The prognosis becomes unfavorable when symptoms of cardiac insufficiency begin to manifest themselves. In quite a number of such cases in the literature sudden death occurred, sometimes without any preceding symptoms on the part of the heart.

63. **Treatment of Obesity by Restriction to Milk.**—Jacob reports eight additional cases of obesity in which the metabolic findings are tabulated during a course of exclusively milk diet at Moritz' medical clinic at Strasburg. These findings and the experiences with a large number of others all confirm the advantages of the strict milk diet in treatment of obesity in many cases. The simplicity of the method, its prompt efficacy while the patients have their appetite appeased and feel well, although the diet is so far below their normal needs—all these factors cooperate in the advantages of this method of reducing obesity. No by-effects or inconveniences have been observed with it. The deficit of protein does not seem to do any harm to the patients under the circumstances.

66. **Determination of Proportion of Epinephrin in the Blood.**—Bröking and Trendelenburg present evidence to show that epinephrin is present in normal blood in a proportion of about 1 to 2,500,000 and that this proportion is doubled and quadrupled in true exophthalmic goiter. In arteriosclerosis, in pregnant women and parturients the proportion persists normal while in chronic nephritis with arterial hypertension it is a little subnormal. They have devised a method for estimating the proportion in the blood which, they state, has proved constantly reliable. The principle of the new method of examination is to pass the blood through the vascular system of the frog kept functioning with Ringer's solution. The frog reacts with a vasoconstriction to epinephrin, and its presence is thus determined. The Ringer's solution is forced into the abdominal aorta of the frog whence it passes through the femoral arteries in the legs and out again through the femoral veins into the abdominal vein whence it passes into a glass cannula inserted in this vein, from which the fluid drips in a constant tempo. The drops automatically record themselves on a reviving drum. A curve of the drops is given showing how when epinephrin or blood containing epinephrin is added to the solution being forced into the abdominal aorta, vasoconstriction at once follows and it is plainly shown by the longer intervals between the drops as registered on the drum. This frog-flushing method has the advantage over other technics that it works physiologically; the epinephrin acts on the nerve terminals of the muscle cells in the vessels—its normal mode of action. The test is so sensitive, at least during the summer, that it reveals even minute proportions of epinephrin, while the same specimen of serum can be used over and over again even when it has commenced to putrefy. The vasoconstriction reaction seems to be specific for epinephrin; none of the numerous other substances tested give this vasoconstriction reaction in the same way and none except in a hundred or thousand-fold concentration, and the vasoconstriction is not so intense and does not subside so promptly.

Therapie der Gegenwart, Berlin

July, LII, No. 7, pp. 289-336

69 Predisposition to Infectious Disease in Children. (Ueber kombinierte [illegible] Diathesen im Kindesalter.)
70 *Diagnosis and T[illegible] Ulcer. (Diagnose und Therapie des perforierten Magengeschwürs.) R. Mühsam.

70. **Perforated Gastric Ulcer.**—Mühsam remarks that there is comparatively little difficulty in diagnosing perforation of a gastric ulcer when there has been a history of stomach disturbances, nausea, oppression independent of the intake of food and acid eructations, even possibly years before. The aspect suggests peritoneal shock; a period of improvement may follow this before the paralysis of the intestines and peritonitis follow. He has found the blood-count of great assistance in confirming the diagnosis; the leukocytes generally run up to 12,000 or 30,000. The Arneth formula is also instructive. The more infectious the stomach content, the greater the danger of progressive peritonitis and the more the body summons its reserves to combat the infection, so that the qualitative changes in the blood-picture with perforated gastric ulcer are even more instructive than the quantitative. He cites some typical cases to illustrate this. In one case a man of 38 was sent to the hospital with the diagnosis of perforated gastric ulcer. He had had occasional mild stomach trouble previously and there was a history of syphilis twelve years before. The pulse was 37.92 C. (100 F.) and the leukocyte-count normal, as also the pupil reflex and the knee-jerk. On the basis of the normal leukocyte-count Mühsam differentiated the trouble as a tabetic gastric crisis and the course of the case confirmed this assumption. In another case a young man with articular rheumatism suddenly developed symptoms suggesting perforation of the stomach, with fever, high pulse and 16,000 leukocytes, but a prompt operation failed to disclose the slightest cause for the peritonitis and the young man soon recovered. In Mühsam's last twelve cases of operative treatment of gastric ulcer, only two of the patients succumbed, while nine died of a preceding series of twelve. His mortality has thus dropped from 75 to 16.6 per cent. He believes that the best means for combating the shock are to close the perforated ulcer and clean out the abdominal cavity, so he operates, if at all, as soon as the diagnosis is certain. As the perforation is so high, the abdominal cavity is more liable to be extensively contaminated than with perforation lower down.

84 *Hemostasis by Momburg's Belt. (Die Momburgsche Blutleere.) A. Steiger.

80. **Management of the Arms with Breech Presentation.**—Sellheim discusses the mechanism of normal breech presentation, the deviations from normal and the ways in which to restore normal conditions, especially by "rotation," illustrating the various points emphasized. The various maneuvers to alter the presentation may bring the arms into very unfavorable positions and systematic rotation, opposite to the direction of physiologic freedom of movement, is able, he says, to bring an arm thrown up over the head down toward the shoulder with other advantages. He does not hesitate to state that rotation deserves to rank high not only as a measure to prepare and aid and render delivery easier but sometimes as the only means to correct the very unfavorable position of the arms.

84. **Hemostasis by Momburg's Belt Constriction.**—Steiger has found records of 163 cases in which waist-line constriction has been used to arrest hemorrhage, including sixty-six obstetric cases. In three cases diarrhea followed, showing some irritation of the intestines, and in one case there was paralysis of the rectum for which, however, the constriction should not be held responsible. In one of 160 cases in the literature there was disturbance in micturition afterward. Complications on the part of the lungs were observed in three cases, and fatal arrest of respiration in one case; but the operator does not venture to decide whether the general anesthesia or the constriction should be incriminated for the fatality. In the sixty-six obstetric cases the method proved a brilliant success in fifty-two, while it failed constantly in nine cases, all reported by a single obstetrician. It is one of the few methods at our disposal for arresting hemorrhage, Steiger adds, in which there need be no danger of infecting the patient.

87 Apparatus (Patellar-Reflectometer) for Measuring Knee Reflex. J. Kitaj.
88 Analogy of Ergotism and Tetany. A. Fuchs.
89 Determination of Functional Activity of the Heart. R. Kleissel.

86. **Diphtheria Antitoxin in Erysipelas.**—Polak reports forty-three cases of erysipelas in which diphtheria antitoxin was used for therapeutic purposes. The result on the whole was a most satisfactory one although the author points out that good results are obtained with every treatment of erysipelas. The temperature falls within forty-eight hours after the injection of the serum and ends by crisis in a few hours. The general condition of the patient is very much improved; the local symptoms of the disease are rapidly lessened in severity and within a few days the patient is well. In complicated cases the further progress of the disease after the injection was not such a favorable one. The author believes that this treatment does much to prevent recurrences. The serum was also used in other streptococcic infections but the result was not such as to warrant further trial. Death occurred in five cases as a result of sepsis, pneumonia and meningitis.

97 Acute Leukemia and Diabetes Insipidus in Status Thymicohypoplasticus. R. Lenk.
98 Trichopilar Muscle Crises in Tabes Dorsalis. A. Neumann.

90. **Rigor Mortis.**—The authors agree with other observers that rigor mortis is caused by a swelling of the muscle fibers due to the retention of acids in excess in the muscles. This swelling of the muscle elements leads to shortening of the muscle fibers and contraction of the muscles. Hitherto it has been quite generally believed that rigor mortis was caused by coagulation of albuminous substances in the muscles. Furthermore, when coagulation of these albuminous substances contained in the plasma does occur the muscles relax. The post mortem changes take place in the muscles and the continuous deposition of acids leads to this coagulation. The experiments performed by the authors which lead them to formulate these conclusions are reported in full.

91. **Treating Tuberculosis with Patient's Sputum.**—After having determined experimentally, in the case of animals, the harmlessness of injecting intramuscularly, intraperitoneally and intravenously the filtrate of tuberculosis sputum, the authors proceeded to make use of the procedure clinically. The sputum of the patient was filtered and toulol added to the filtrate. This mixture was injected subcutaneously, only 2 c.c. being given at the commencement of the treatment. A second injection was not given if a reaction followed the first until four days after the subsidence of the reaction. A large amount was injected the second time. The reaction following these injections is at first local in character, consisting in reddening of the skin and deep-seated swelling. The râles in the lungs are increased in intensity. The general reaction consists in slight elevation of the temperature, as occurs when tuberculin is injected. This elevation is first noted in from four to six hours after the injection and does not exceed 2 degrees. It subsides both suddenly and gradually in different cases. The patient complains of lassitude, headache and expectoration is increased. After these symptoms have subsided the patient feels better, eats better and coughs less. In several cases there was a distinct gain in weight after four injections, which had not previously been noted with other treatment. Only such patients as did not respond to tuberculin treatment were treated by sputum filtrate injections.

92. **Culture Medium for Differentiating Cholera Vibrios.**—For the purpose of differentiating the cholera vibrio from the colon bacillus, the authors made use of a blood-alkali bouillon which was really an adaptation of Deiudonne's blood-alkali agar. To 100 c.c. of neutral bouillon are added 25 c.c. of blood-alkali albumin. The mixture is exposed to a temperature of 50 C. for three hours and 37 C. for twenty-four hours. It is important not to use the mixture too soon because when this was done the results were invariably unsatisfactory. The cholera vibrio grows well on the medium in pure culture. The colon bacillus does not grow at all. Therefore, this medium is particularly suited for securing the cholera organism from the stool.

94. **Sterilizing Rubber Gloves.**—The authors subjected rubber gloves that had been infected with various organisms to sterilization in the autoclave at a temperature of 100 C. for thirty minutes, with the following results: five pairs of gloves infected with streptococci remained sterile. Five pairs infected with staphylococci also remained sterile. Of four pairs infected with the *B. pyocyaneus*, three remained sterile, the fourth pair showed a growth of pyocyaneus. In the case of six pairs infected with *B. subtilis*, sterilization proved ineffective. The same was true of five pairs infected with *B. mesentericus vulgatus*. It is apparent, then, that a thirty minute exposure to 100 C. in the autoclave without pressure is not sufficient to effect sterilization. In a second series of experiments, infected rubber gloves were exposed to a temperature of 120 C. with a pressure of 1 atmosphere for thirty minutes. All the gloves remained sterile.

96. **Action of Thyroid Extract.**—The action of thyroid extract was very thoroughly studied by the author and he reaches the conclusion that it has a characteristic effect on the heart muscle and cardiac nervous apparatus. In the case of the dog, this is manifested by lowered blood-pressure and increased frequency of pulse-beat. The former is the result of direct weakening of the heart action by vasodilation. The acceleration is believed to be due to the irritation of the accelerating nerve apparatus. Further, a small dose of alcohol disturbs the thyroid acceleration and depression. A large dose increases the depressor action of thyreoiodin. The author cautions against the indiscriminate use of thyroid extract; particularly in combinations with other substances.

105 Biologic Reactions in Pellagra. M. V. Carletti.

99. **Simplified Tuberculin Skin Test.**—Barabaschi rubs the region with alcohol until the skin is red. Then in the center of this area he spreads a thin layer of tuberculin without rubbing it in and lets it dry. In 114 cases in which he has applied this test there never was any general reaction, while the local reaction seemed to be a reliable index of an active tuberculous process even when the process was in its incipiency. He gives the details of eighty-nine cases to show the reliability of the test. His previous communication was summarized in THE JOURNAL, Sept. 10, 1910, page 977.

106. **Origin of Neoplasms.**—Fichera here concludes the report of his research in this line which was mentioned in THE JOURNAL, June 10, 1911, page 1769. The communication issues from the surgical clinic at Rome in charge of Durante, and is the sixteenth Fichera has published on the origin of cancer as a result of premature senility of the cells, and treatment by what he calls histogenous chemotherapy; that is, with embryonal tissues as the opposite extreme. Besides the facts and experiences cited by Pearce Gould, there are others which he claims prove his statements that study of the efficiency of unaided Nature to effect a cure in certain cases of cancer is the only means to learn how to cure malignant disease. Several investigators have confirmed the destructive action on tumor cells of normal serum while the tumor cells do not seem to be influenced by even prolonged contact with the serum from persons with malignant disease. Gussio of Rome has found that fragments of rat sarcomas kept a day in blood-serum at body temperature or implanted in the peritoneal cavity of sound rats never take root and grow, while they do take root when the serum in which the scraps were kept had been taken from a cancer rat. Study of the variations in the tumor cell-destroying property of the serum may give interesting results, especially systematic investigation of the serum of roentgenologists who are so often victims of cancer. This property declines toward the end of a pregnancy, which confirms anew the principle that active development of fetal or neoplastic tissues is always accompanied by a lower cytolytic index in the host. Fichera cites Hochenegg's experiences with cancers developing at once after a pregnancy, and Fichera has encountered a case in which a cancer developed immediately after a pregnancy but was successfully removed. Seven years later another cancer developed under similar conditions after another pregnancy. He sums up his theory as the tumor-producing loss of balance and cell-producing chemotherapy,

equilibrio oncogeno e chematerapia istogena. The extract he uses is made from two to six months' fetuses from the maternity, triturated and placed in salt water until autolysis is *complete.*

119 *Technic for Operative Treatment of Peritonitis. L. Kraft.
June 14, No. 24, pp. 649-680
120 *Pathogenesis of Glaucoma. J. Bjerrum.

119. **Treatment of Peritonitis.**—Kraft is an advocate of suturing the peritoneum at once after having swabbed out all effusion or rinsed the cavity clean, and his series of parallel cases with and without drainage apparently *confirm* the superiority of this technic. It is not applicable, of course, with a gangrenous process or suppuration in the connective tissue below the peritoneum. But when it is possible to suture the peritoneum at once, normal peristalsis generally starts up again while a drain checks it. Active peristalsis promotes absorption of any peritoneal effusion and the bowels resume normal functioning, all of which is liable to be lacking when the peritoneum is drained.

120. **Glaucoma.**—Bjerrum presents evidence to sustain the assumption that glaucoma is not exclusively merely exaggerated intra-ocular pressure but that *an irritative process is involved besides.* This irritation seems to affect essentially the ciliary body. Excessive secretion follows, and this hypersecretion is the cause of excessive intra-ocular pressure. The primary irritation is probably of a toxic nature. He cites some typical cases to show this connection and the lesions encountered.

CLINICAL PHYSIOLOGY—AN OPPORTUNITY AND A DUTY

YANDELL HENDERSON, Ph.D.
Professor of Physiology, Yale Medical School
NEW HAVEN, CONN.

The time has come for the formal recognition of clinical physiology as a distinct subject and a field of work of the first importance. More or less inchoate, more or less dimly recognized, it already exists. The function which I wish to assume toward it to-day is rather that of a priest at the christening than that of a midwife at the birth of this latest-born and most neglected of the family of the medical sciences. I wish to give it the distinction of a name.

In the progress of medicine during the past decade, no feature has been more striking than the rapidity with which the advances in theoretic knowledge made in the laboratories of pathology and bacteriology have been adapted to the uses of clinical medicine. Physiology, on the contrary, has to a large extent led a life of mere self-development—like a proud virgin, beautiful, cold and sterile. I know that I risk the vigorous dissent of other physiologists in making this criticism. But I believe that it is needed not only for the good of medicine but for the best interests of physiology itself.

Science uncontaminated by any contact with the practical business of the world has in recent years been extolled in many an eloquent period. Priceless in their practical results have been the investigations made by great thinkers with no practical end in view. Nevertheless, I hold that none of the sciences, certainly none of the medical sciences, can long remain wholly divorced from contact with practical aims and yet continue fertile.

The appeal of clinical physiology is both to physiologists and to clinicians. Physiologists now and in the next few years will find their richest and most fruitful problems in the field of clinical, rather than in that of purely abstract, physiology. In the golden age of physiology our great predecessors, Claude Bernard, Brown-Séquard, Marey, Ludwig, Fritsch and Hitzig, and many others worked at topics which were at that time essentially problems of clinical physiology. Where in the literature of their day will you find anything to compare in ineptitude with the ponderous discussion of the mathematics of a membrane manometer, on which some of their successors in Germany now spend their time? Had not Voit's life work on nutrition a broadly utilitarian object? Was not Bernard working at the problem of diabetes when he discovered glycogen? And at animal heat with the problem of fever in mind, when he found the vasomotor nerves? We have dug enough ore from the depths for the present. Let us devote ourselves for a time to extracting some of the gold which it contains.

To clinicians in nearly all departments, physiology offers to-day a brilliant opportunity. The progress of medicine in overcoming the secrets of disease is like the siege of a walled city. The clinicians are the infantry. The laboratory workers are the sappers and miners, the heavy siege artillery and the aviation corps. It is useless to hurl infantry against an unbroken wall. When, however, a mine has been sprung or a bastion battered down, then is the time when good generalship will lead the infantry to the assault through the breach and over the fallen ramparts. The great breaches of the past few years, into which the infantry have stormed, have been those opened by pathology and bacteriology. Meanwhile physiology has not been idle. It has burrowed under and overthrown many of the strongest towers. What is needed now is the massed assault of the infantry. In simple words, there is in physiology to-day a great mass of knowledge and a wide range of methods readily adaptable to clinical uses and needs. If clinicians will acquaint themselves with this knowledge, and adopt, adapt and employ these methods, they will be able to march rapidly over obstacles now insurmountable.

Such a development of clinical physiology might well be the greatest event in the progress of medicine during the second decade of the twentieth century.

What the entire volume of clinical physiology should be in the future may most easily be shown by instancing such of its chapters as might be written even now. Such a chapter might be written about the clinical use of the sphygmomanometer, the significance of its measurements and the conceptions of circulatory functions which center in it. How valuable are these conceptions and measurements I need not emphasize before this audience! That which should be emphasized is the fact that physiologists began measuring blood-pressure in millimeters of mercury more than half a century ago; yet the clinical modification and utilization of the method is a matter of yesterday—perhaps I should rather say of to-day, or even to-morrow. Thus, by this example, it takes at least fifty years for a physiologic conception or method to find its way from the laboratory to the clinic. Many pathologic and bacteriologic methods complete the arduous journey in as many weeks.

It is only five years since I had the pleasure of attending a meeting of the British Medical Association at Toronto and of sitting in a great hall packed with clinicians, listening with open-mouthed interest to the wonderful news that the blood was under pressure in its vessels, that the pressure could easily be measured and

---

* Chairman's Address before the Section on Pathology and Physiology, at the Sixty-Second Annual Meeting of the American Medical Association, held at Los Angeles, June, 1911.

that such measurements have a meaning. On this occasion a number of eminent authorities who had crossed the broad Atlantic, or traveled thousands of miles from the four quarters of Canada and the United States for this special purpose, thought it necessary to explain in words of one syllable how the heart pushes the blood through the arteries and how this pressure is measured by the raising of mercury in a tube of glass. Then arose one most eminent in authority who informed the audience in effect that using an instrument for such a purpose was all "bosh." For himself, he believed that the "tactus eruditus of the trained finger" told any competent physician or surgeon all that he needed to know!

I suppose that no one, however eminent, would dare make such an assertion to-day. We do not now have to explain what arterial pressure is. But turn for a moment from the clinical aspects of the circulation to those of respiration. Here is a function of the first importance; a function subject to manifold alterations in health and disease; easy to observe, relatively easy to measure; a function about which physiologists have locked in their laboratories a considerable amount of information. Yet look through all the hundreds of well-appointed hospitals between Los Angeles and Eastport in the state of Maine; look in all the elaborately equipped consulting rooms of all our eminent internists. Where will you find an instrument for anything more than the crudest observation and measurement of respiration? Nowhere, I believe! What do the clinicians of to-day—even the most learned—know of respiration? Next to nothing! And this little is mostly wrong.[1] If a patient pants for breath do not most of them order as many gallons of oxygen as his purse will allow to be blown off somewhere in the neighborhood? As well might they burn so many Chinese prayers printed on rice paper—except that it is profitable for the concern that supplies the oxygen. If, on the contrary, a patient's respiration is failing, oxygen may likewise be ordered; and a grim humor attaches to the fact that this oxygen, in order to comply with the requirements of the Pharmacopeia, has been carefully freed from every trace of carbon dioxid—the one substance which might act for a time to restore the respiratory center to its normal activity. Great is the medicine of to-day in its knowledge of man's parasites; great in its acquaintance with the appearance of his tissues after he is dead. But do we not lack an adequate comprehension of the functions of man himself, and a control of the working of the machine while, although somewhat damaged, it is still a "going concern?"

I am convinced that the now unutilized opportunities which modern physiology offers are so promising that any capable and well-trained physician or surgeon, if he will but take the trouble to acquaint himself with some one line of the subject—say respiration for example—and to work at it in connection with his practice, may make a notable contribution to practical medicine. What can be done in many lines may best be shown by instancing what has been done in a few. Consider the work of James Mackenzie, at first only a country doctor. With no better opportunities for work than a rural practice afforded he took the sphygmograph and applied it clinically. To-day his work on the application of graphic methods to the clinical study of diseases of the circulation stands as one of the finest chapters of clinical physiology.

The electrocardiogram is affording a similar opportunity for advancement in the clinical physiology of the heart, an opportunity which fortunately a number of internists in this country have seen and utilized. The new work of Hirschfelder of the Johns Hopkins School on diseases of the heart and aorta is throughout essentially a treatise in clinical physiology.

On the side of surgery one of the most brilliant events of the past few years has been the development of methods allowing a ready access to the interior of the thorax. The work of Sauerbruch and Brauer, and of the other surgeons who have worked in this field, is a striking example of the profitableness of clinical physiology. So also is the work of Crile on surgical shock, and that of Cushing on the functions of the pituitary gland, normal and abnormal.

In a similar manner I might illustrate the sort of work which I believe that physiologists ought to do by examples of what some have done. Here may be mentioned the work of Erlanger on heart-block; of Cannon, not only on the normal movements of the stomach and intestines, but also on those after the performance of gastro-enterostomy, and of Meltzer in developing intratracheal insufflation from a method of mere laboratory interest into one which may prove of the greatest clinical utility.

All of these illustrations are drawn from the physical side of physiology. The physiologic chemists of to-day would easily afford ten times as many examples. In fact, the greater part of the flood of work which at present is almost swamping the journals of physiologic chemistry is essentially of this, to my mind, the right sort. It is directed to the solution, not of mere esoteric problems, but of topics of broad and pressing medical and human interest—diabetes, metabolism in disease as well as in health, and to those problems of nutrition which are of such tremendous import for the welfare of mankind.

It was a fortunate day for medicine when Emil Fischer turned his attention to the proteins. Almost at a stroke he lifted the pure and esoteric problems of biochemistry to a plane on which the great majority of chemical physiologists are incapable of working. Only a specially trained organic chemist can do this work. So our chemically-minded brethren, greatly to the profit of medicine and of their own scientific fortunes, have been forced to devote themselves to the cultivation of fields which will bear and are richly bearing fruit for to-day and to-morrow, rather than to that deeper ploughing and sowing from which the slow-growing harvest will indeed be of priceless value, but chiefly for generations yet unborn.

For the development of clinical physiology in America three conditions seem to be of special importance:

1. Internists and surgeons, and especially the professors of medicine and surgery in our medical schools, must be more interested, better trained and more widely read in physiology. It were better if they read less in the clinical and more in the scientific journals; better if they talked and practiced less, and investigated a great deal more.

2. Physiologists must assume the duty of teaching not only normal but also abnormal physiology. Both, in my opinion, should be taught in the second year of the medical course and as successive parts of one and the

[1] So far as I am aware, the first paper ever written by an American clinician, based on a study of respiration in disease by precise physiologic methods, was presented as the oration in medicine at this meeting of the American Medical Association by Dr. C. F. Hoover.

same subject. We cannot leave this for the pathologists to do. A man trained by autopsy and microscope is inevitably a morphologist. Just in proportion as he is fitted to deal with morphologic processes, he is unfitted to handle and expound functions of a physical nature—unless, of course, he happens to be an all-around genius.

3. Finally, I hold that in the future students who are being trained to be physiologists, whether in the field of physical and nervous or of chemical physiology, ought to have the M.D. degree. In our better medical schools the improvement of the curriculum in the last few years has been so marked that even the clinical courses have, to a great extent, lost that deadening influence on the students' ability to think scientifically which they formerly exerted. Furthermore, the elasticity introduced into the curriculum by the elective system, as practiced at Harvard and at Johns Hopkins, affords opportunities for the student who plans to be a physiologist to take little of what he will not need and to devote himself largely to his special interests.

I do not regard the Ph.D. degree alone as insuring a sufficiently broad training for a physiologist, either in the chemical or physical line. It is true that many American physiologists are merely doctors of philosophy. I am such myself. But I know, by the sad experience of years wasted in filling in the gaps in an utterly insufficient technical training, how great a handicap this is. Any doctors of philosophy who profess a different view I am compelled to regard as like the fox in the fable who lost his tail. If they, like this cunning animal, claim that a condition of taillessness is an advantage, I would like to warn all the young physiologic foxes to beware. Grow a good bushy tail in the form of an M.D. after your name, and let no tailless old fox beguile you out of growing it.

400 Prospect Street.

SPINAL FRACTURES

OPINIONS BASED ON OBSERVATIONS OF SIXTEEN OPERATIONS *

A. F. JONAS, M.D.
OMAHA

There are no graver injuries than fracture of the bony structures of the spinal column. No class of fracture presents more difficult problems for solution. In none is there greater uncertainty as to diagnosis, management and ultimate outcome.

Surgeons who have had a considerable experience with spinal fracture have not become wildly enthusiastic as regards treatment and prognosis. If a surgeon has operated frequently, he has learned that a fracture dislocation usually causes a partial or complete division of the cord, and that complete recovery is extremely rare. He may count a considerable number of operative recoveries and some patients who have regained a partial functional activity, but complete restoration of function is uncommon.

However, when we carefully review our cases and consider the extensive destruction of the cord in a large percentage of instances and the long periods of delay that are only too common before active interference is resorted to, and again when we recall the unusual handling of many cases of spinal fracture, while being transported home or to the hospital, often increasing the bony displacement and cord compression and augmenting the laceration of meninges and spinal vessels, it is not strange that our results are no better.

I desire to record briefly my personal experiences with injuries to the spinal column. During a period of thirty years there have come under my observation forty-two cases of spinal injury that involved the bony structures of the spinal column, as shown by spinal deformity and complete motor and sensory paralysis of all the structures below the seat of fracture. In this number are included all that I have examined as my own cases and those that I have seen in consultation with other practitioners. Of this number only sixteen have come to operation. In the light of our modern conceptions of the surgical treatment of compression fractures, too many of these have been allowed to be unoperated on. And yet those of us who have witnessed much of accident surgery and particularly of spinal fractures, and have learned to know of the severe crushing of the cord and its membranes in a large percentage of cases, understand too well the hopelessness of the greater number of them. Not only are surgeons not enthusiastic about spinal operations, but the laity is loath to give its consent, owing to the well-known uncertain prognosis. You and I have been compelled to admit that the final outcome is uncertain when we advise a laminectomy as the only chance. We cannot even give an approximate estimate as to the prospects. We have no means of knowing how extensive is the traumatism to the cord and its envelopes. We are fairly certain, in a given case of deforming fracture with paralysis, that the cord is certainly damaged and still we cannot ascertain, with certainty, if it is compressed or lacerated or completely divided. It may be fair to assume that the cord is completely divided where there is a pronounced angular deformity and complete motor and sensory paralysis, and yet moderate cord injury has been found with extreme posterior angular deformity. We may say that the spinal deformity does not always indicate the extent of the cord injury. Consequently we have to deal with an uncertainty. I have met with cases in which there was no spinal deformity and yet there existed complete paraplegia and a laminectomy demonstrated actual cord destruction. And again I have examined one case of marked posterior lumbar deformity causing complete paraplegia immediately after the accident with entire relief of paralysis after traction had been made on head and pelvis and a partial restoration of the deformity by digital pressure. The patient was able to walk about in spite of marked angular deformity. Between these two extremes we have every variety of clinical picture presenting a great array of traumatisms that are often at variance with the physical findings. The traumatisms may amount to a simple transient concussion or may consist of a complete division of the cord. Unfortunately the vast majority of fracture dislocations have produced partial or complete cord division. [illegible] ny operative work complete division occurred in [illegible] reater number of cases and in none of them, [illegible] e exception of an occasional temporary imp[illegible] id I see a patient completely recover. W[illegible] ed that recovery of these cases was absol[illegible] Practical experience and experimen[illegible] ed to indicate that the spinal cord n[illegible] ntil the publication of Hart and Stewart's case[1] of severed cord in the dorsal region operated on by them in 1901. We had been taught by Ludwig, Wiesman, Ballance and others that

ganglionic non-neurilemmatous nerve cells once destroyed never regenerated, that a complete division of the cord, at any point between the atlas and twelfth dorsal vertebra, was hopeless, because in this part of the cord, the cell elements were non-neurilemmatous. We had learned that regeneration was possible only in the cauda equina and in the spinal nerve roots external to the cord which meant that, when improvement did take place, it was due to the nerve anastomoses between the spinal segments above and below the injury. All experimental research seemed to coincide with clinical observations that a divided spinal cord never underwent complete anatomic and physiologic restoration, that we were quite unprepared for the report of Hart and Stewart's case. They had done a myelorrhaphy in a cord divided by a bullet and, while the outcome was not a complete restoration of function, the result seemed to indicate, at least, a partial regeneration of the cord and we began to have some doubts as to our well-fixed convictions regarding regeneration.

This observation was sufficient, however, to awaken the hope that there was some error in the experimental findings of the workers in this field. More recently Estes has reported two cases of resection of a completely divided cord where a myelorrhaphy had been done, with marked improvement in both cases, so that spinal fractures are apparently not as hopeless as past experience seems to indicate. Later observations of these reported cases show that recovery was not complete in any of them; while improvement was marked and gratifying to a certain point, motion and sensation did not become normal and we are obliged to admit that, after all, these cases have not changed our scientific knowledge and that the non-neurilemmatous elements of the cord do not regenerate and the improvement must be attributed to the extra-spinal nerve anastomoses.

The important problem consists in determining what to do in a given case. We have to do with a part of the human anatomy that seems to have been provided in its construction, with every safeguard to prevent injury; a column made up of short, strong, bony segments held together by tremendously strong ligamentous and muscular bands: a flexibility secured by three anteroposterior curves, a series of twenty-four ribs insuring a wonderful lateral support. It is clear that a tremendous force, either direct or indirect, is necessary to effect a fracture.

We have learned that direct violence often produces a simple fracture, which means fractures of the transverse processes, the laminæ, pedicles and spinous processes and sometimes the bodies. These fractures sometimes cause comparatively trivial disturbances, which occasionally consist only of an irritation of spinal nerve roots and at other times extensive cord destruction with complete paralysis of motion and sensation due to pressure of bony fragments or hematomas and later to transverse myelitis. The clinical manifestations are so variable that the diagnosis is often only a matter of speculation.

Indirect violence producing forcible bending forward, is caused often by the falling of weights on the back while working in a stooping position (like a coal miner, where masses of coal fall from the ceiling of a mine), producing comminuted and complicated fractures. They are attended by extensive laceration of muscles, ligaments, cord envelopes, spinal nerves, and the cord itself and considerable hemorrhage. The vertebral bodies may be crushed, the pedicles fractured, the bone fragments are usually displaced and there exists the inevitable cord lesion usually complete division and the nature of the injury appears quite clear. But let us for a moment consider the average spinal injury.

We are presented with a recent case. We are informed as to the nature of the accident, direct or indirect violence. There is immediate and complete motor and sensory paralysis below the point of injury. There may or may not be a posterior angular deformity, or one or more movable spinous processes, the local pain may be intense or mild or absent. There may be severe lancinating pain in the course of the spinal nerves, springing from the seat of injury or immediately above it. Tendon reflexes may be exaggerated, enfeebled or absent. Now we ask ourselves what structures are damaged? We may be certain that there is cord compression, but can we be certain whether the pressure is due to bone fragments or to hematorrhachis or hematomyelia? If we see the case at a later period, a few days or a few weeks or months later with the same train of symptoms to which have been added the following, the bladder and anal sphincters are paralytic if the lesion is high, there may be priapism; pain at seat of injury may have increased and may have become lancinating and peripheral; trophic changes are unmistakable and vasomotor disturbances are marked. There are secretory changes in the skin, ankle-clonus and planter reflexes uncertain. Babinski's sign, although absent in early cases, may have developed. Now, are we certain of the exact nature of the injury? It is true that we are fairly certain in the presence of the clinical picture containing the greater number of the above symptoms, that we have a grave injury to the cord. But in the present light of our knowledge, we cannot state with certainty whether we have compression or a partial or complete division of the cord.

In dealing with spinal fractures, especially those that we have operated on, it was possible in the majority to state that the cord was injured, but it was not possible to know to what extent before the spinal canal was opened. In some, where a destruction of the cord seemed certain, the operation disclosed a large clot pressing on the cord and in others where one or two spines were depressed, a laminectomy revealed pressure, but no destruction, and again in the presence of moderate deformity a single sharp fragment had caused extensive meningeal and cord laceration. In one case with a marked posterior angular deformity involving the sixth, seventh and eighth dorsal vertebræ and complete and immediate motor and sensory paralysis, a complete destruction of the cord, at point of injury, seemed certain. It was found, on opening the spinal canal, that the cord was compressed but not destroyed. No visible lesion could be made out. A laminectomy was done and a complete restoration of motion and sensation ensued. Now in the presence of this wide discrepancy between clinical and anatomic findings, what are we to do? I have wavered between the extremes of non-interference on the one hand and operative intervention in all cases of spinal injury whose chief clinical manifestation was paraplegia. It has been difficult to carry out the latter plan in practice, partly on account of the deeply rooted prejudice of the laity against operations, owing to the well-known high mortality in spinal fracture, and the uncertainty of the outcome after surgical interference. Then the surgeon himself had to confess that a spinal injury with paralysis and no deformity does sometimes recover. In cases where there may have been a concussion with no tissue destruction, recovery may occur in a few hours or days. There may have been an extra dural clot which may have become absorbed, and restoration of function may be complete in a few days or weeks.

There seems to exist much uncertainty with individual operators as to what is best to do. Very few or no surgeons can count their spinal operations by the hundred, and to lay down positive working rules for our guidance may be hazardous and yet we have several unmistakable indications that we cannot ignore. When carefully studying only a part of the published cases, we find that all operators must agree as to the uncertainty of the anatomic findings in most cases, especially where undoubted deformity exists. There may be an extensive osseous lesion with little or no cord destruction, or an apparently limited bony lesion and much cord destruction. We all agree that the osseous lesion is no guide to the extent of the intraspinal condition.

Now in view of this uncertainty there appears only one thing to do and that is to open the spinal canal in all cases of spinal injury with deformity and paralysis. Do an exploratory laminectomy. Accurate asepsis and exact surgical technic have made operative intervention a safe procedure. It should be done immediately and if possible as near the place of accident as can be. Much damage can be done while the patient is being transported. Rough handling or long continued jolting over a rough road can increase the vertebral displacement, augmenting a pressure or a laceration, increasing the damage and thereby changing a curable to an incurable condition. I have known of at least one case in which this occurred, as will be noted in the following record of cases with operations. Delay is usually dangerous. While there are recorded some cases in which later operation was done for compression of the cord, they are the exception. Many patients have been operated on after lapse of weeks and months, who were not benefited on account of degeneration of the cord though the initial lesion consisted solely of compression. Therefore it would seem that the best practice is to open the spinal canal as soon as the diagnosis is made; delay in actual cord injuries is not advisable on account of the liability of early degeneration of cord elements.

I have attempted to arrange my cases under the following heads:

1. Contusion of the cord due to a momentary pressure of a fracture of one or two laminæ, where the spinal arch springs back into place almost instantly causing paralysis but leaving only moderate external deformity—in some instances a movable spinus process.
2. Compression in the presence of non-reforming fracture due to hemorrhage in the spinal canal (hematorrhachis).
3. Compression due to hemorrhage both on and in the cord (hemorrhachis, hematomyelia).
4. Compression without destruction of cord elements.
5. Partial destruction of the cord at the seat of injury.
6. Total destruction of the cord at the seat of injury.

The following cases are not arranged in the order in which they came under observation but according to their pathologic findings. Only those that came to operation appear. No cases of concussion or shock of the spinal cord are here recorded; only those are discussed in which the clinical findings indicated a fracture of the osseous structures.

1. Contusion of the cord due to a momentary pressure of a fracture of one or two laminæ, where the spinal arch springs back into place almost instantly, causing paralysis but leaving only little external deformity, in some instances a movable spinous process.

Under this head we will find two cases.

Case 1.—A. B., aged 45, laborer, while occupied in the construction of a building, fell from the second to the first floor striking on his back. He was picked up unconscious and carried to his home a few blocks away. He regained consciousness in a few hours, but found himself paraplegic from the nipples down.

Examination.—I saw him ten days later at the M. E. Hospital. There was found complete abolition of motion and sensation from the nipple line downward. There was no control of the sphincters. The sixth dorsal spine was found to be freely movable.

Operation.—An operation was advised and quickly agreed to. A trap door skin incision and blunt separation of the muscular and ligamentous structures exposed the spines and laminæ of the fifth, sixth and seventh dorsal vertebræ. The sixth spine was loose and it was removed. The laminæ of all the vertebræ seemed firm and not depressed. On close examination, however, the left lamina of the sixth vertebra showed a fissure and the bone was slightly depressed. The lamina was removed with a chisel. The meninges appeared thickened with a hemorrhagic infiltrate extending slightly into the cord. The parts were gently flooded with normal salt solution, clearing away much of the infiltrate. It appeared that the lamina on one side was fractured and had been crowded down on the cord, then instantly sprung back into its normal position. There was very little tendency for the incised meningeal margins to separate and no suture was used. The wound was closed.

Result.—There was gradual return of sensation of motion in the course of two months, so that he was able to leave the hospital, walking well, with crutches.

Case 2.—C. A., laborer, aged 40, fell from a wagon, striking on his back. There was temporary mental confusion but no unconsciousness. He was unable to move. When assistance arrived, it was found that he could move his arms fairly well but his lower extremities had lost all movement and sensation.

Examination.—I saw him at his home, four weeks after his injury. All sensation and motion absent below the ensiform appendix, both sphincters incompetent. A bed sore on the sacrum. The fourth and fifth dorsal spines were movable and manipulation was painful.

Operation.—(At home.) The spinal canal was opened as in the preceding case. The spines together with the lamina were easily removed after dissections of the soft parts. It was found that the laminæ were not compressing the cord, but evidentally had momentarily done so. There was a hemorrhagic infiltrate in the meninges and slightly in the cord and several small clots between meninges and laminæ. Flooding with normal salt solution and careful swabbing, cleared the field fairly well. Several sharp bone spiculæ were clipped away. Meninges not sutured. The wound was closed.

Result.—There was gradual return of sensation and motion. In a year, with the aid of a cane, he was walking.

The foregoing two patients might possibly have recovered without operation, but it was impossible to estimate the extent of the lesion before the spinal canal was opened.

2. Compression in the presence of non-deforming fracture due to hemorrhage in the spinal canal. (Hematorrhachis.)

There was only one case of this nature.

Case 3.—F. D., farmer, aged 35, fell from a hay-loft a distance of about ten feet, falling on his back. There was complete motor paralysis when he was found an hour later. Sensation was diminished but not absent. It disappeared, however, in 24 hours.

Examination.—I saw him ten days later at his home where all preparation for an operation had been made. The patient stated that he did not become unconscious at the time of the accident. And he thought, but was not absolutely certain, that he could move his legs for a few moments, but that he did not try again on account of the great pain in the back. All sensation and motion were absent below the epigastrium;

there was very little sphincteric control. There was much ecchymosis over the middorsal region, but no evidence of vertebral fracture. Considering that compression was apparently not instantaneous and the absence of deformity, we concluded that we had to deal with a hematorrhachis.

Operation.—The patient was anxious for an operation. Accordingly the spinal canal was laid open by removing the laminæ of the sixth and seventh dorsal vertebræ. A large, rather firm blood-clot was found; it was extradural and was partly picked away with an anatomic forceps and partly washed away with a stream of normal salt solution. The cord coverings were found uninjured. The wound was closed.

Result.—The operative recovery was uneventful. Sensation and motion gradually returned. In a year he was able to walk fairly well with a cane.

3. Compression due to hemorrhage both on and in the cord. (Hemorrhachis, hematomyelia.)

Under this head there were two cases.

Case 4.—M. S., farmer, aged 32, fell from a tree, striking the back, middorsal region. He was found half an hour later, with complete paralysis of both lower extremities.

Examination.—I saw him a week later. Complete paraplegia. No sensation or motion below nipple line. Sphincters paralytic. Much tenderness over the third, fourth and fifth dorsal vertebræ. Spines slightly movable and depressed.

Operation.—The spinal canal was opened; the laminæ were pressing on the cord. They were removed. An extradural clot was found, the meninges seemed contused. The longitudinal incision exposed the cord and more blood-clots beneath the dura which appeared to occupy a part of the cord itself. They could not be all washed or swabbed away. The meninges were not sutured. The wound was closed.

Result.—The patient died in one week, apparently from meningitis.

Case 5.—D. F., bricklayer, aged 40 years, fell from a scaffold striking his back on some bricks, and became unconscious. He was removed to his home, regained consciousness in a couple of hours, having lost motion and sensation from the costal arches down.

Examination.—I saw him about ten days later. There was complete absence of motion and sensation below the costal arches. Both sphincters were incompetent. There was a slight depression over the seventh and eighth dorsal vertebræ.

Operation.—The spinal canal was opened; the laminæ of the seventh and eighth dorsal vertebræ were removed. The findings were similar to those in the preceding case.

Result.—The patient made a good operative recovery but died two months later, with no improvement in motion or sensation.

4. Compression without destruction of cord elements.

Under this head we had one case.

Case 6.—M. J., laborer, aged 36. While engaged about a building during the course of construction, a beam fell, striking him across the shoulders, doubling him forward. He was picked up unconscious. Four hours later, when consciousness recurred, he found himself paraplegic.

Examination.—I saw him about two weeks later. Temperature 103 F. Pulse 130. Paraplegic. He complained of great pain in his back. I found distinct posterior angular curvature, sixth, seventh and eighth dorsal spines prominent.

Operation.—An immediate laminectomy was done. The meninges and cord were apparently uninjured. The meninges were incised but the cord was found normal; two catgut sutures closed the coverings. The wound was closed and dressed. A plaster cast was applied with aid of a Bradford frame.

Result.—The operative recovery was uneventful. There was gradual improvement. At the end of six months he could walk with a cane.

5. Partial destruction of the cord at the seat of injury.

Under this group there were four cases.

Case 7.—O., farmer, aged 30, while diving into a shallow swimming hole, struck his head on the bottom, he was helpless immediately and it was with difficulty that he was rescued by his companions. All his extremities were paralyzed, the upper as to motion and the lower as to motion and sensation.

Examination.—He was brought to the M. E. Hospital ten days later. There was absence of motion in both upper extremities and partially as to sensation. In the lower extremities and trunk, there was no motion nor sensation. Bladder and rectal sphincters were incompetent. The neck was stiff, movements caused pain. A skiagram indicated a fracture, displacement of the fourth and fifth cervical vertebræ.

Operation.—Through a longitudinal incision, the loose laminæ were easily removed after the soft parts had been dissected off. The dura was lacerated by the sharp, fractured laminæ. The posterior columns were partly torn. After cutting away the lacerated tissues, the wound was closed.

Result.—Operative recovery was uneventful. He gradually regained sensation and motion, first in the upper extremities, then partially in the lower extremities. One year after the accident, he was able to stand on his feet but not to walk. He was able to get about in a wheel chair.

Case 8.—S. P., aged 40, brakeman, fell from the top of a box car, fracturing the laminæ of the fourth and fifth dorsal vertebræ, causing complete paraplegia.

Operation.—He was seen twenty-four hours after the accident. Laminectomy revealed torn meninges, a destruction of the left lateral half of the cord. Torn tissues were trimmed with scissors. The wound was closed with silk-worm gut drain.

Result.—The patient died one week after operation, from meningitis.

Case 9.—P. D. H., aged 29, brakeman, fell between two standing freight cars, striking the lower dorsal region on the rail. There was immediate and complete paraplegia.

Operation.—He was seen the day of the accident. I performed laminectomy of the seventh and eighth vertebræ. Partial destruction of the posterior columns was found. The lacerated structures were trimmed with scissors. Irrigation. Closure of wound. Silkworm gut drain.

Result.—There was recovery from the operation but no improvement, and he died in six weeks.

Case 10.—F. J., laborer, in a runaway, was thrown from his wagon, falling on his back. Immediate paralysis of both lower extremities resulted.

Operation.—When I saw him, about a week later, the ninth and tenth dorsal spines were movable. Laminectomy showed lacerated membranes and destruction of posterior columns. After removal of lacerated tissues and irrigation, the wound was closed. Chromic gut drain.

Result.—Operative recovery. For two months there was return of sensation, then he rapidly became worse and died ten weeks after his operation.

6. Total destruction of the cord at the seat of injury.

Under this head there were five cases of fracture and one a gunshot wound with complete division of the cord. None of these patients recovered. All died in periods varying from one week to eight months. In none of them was there improvement in sensation or motion. Four of them developed large bed sores. Death seemed to be due to gradual exhaustion, emaciation, and sepsis that apparently originated in the bed sores. One patient, with a marked posterior angular middorsal deformity and complete transverse destruction of the cord, died one week after his operation.

One patient, in whom a gunshot wound fractured the lamina of the sixth dorsal vertebra and lodged in its body, completely dividing the cord, lived four months.

Case 11.—C. D., aged 32, a coal miner. While at work, a mass of coal fell on his back, bending him forcibly forward. When removed from the mine, he was completely paraplegic.

Operation.—I saw him about five weeks later. Laminectomy of eighth, ninth and tenth dorsal vertebræ. Cord crushed.

Lacerated tissue was trimmed away leaving a defect of one-half inch. Suture of the ends of the cord was attempted but failed. Wound closed. Chromic gut drain.

Result.—Death in three weeks.

CASE 12.—J. D., aged 31. While at work in a stone quarry a stone fell on his back, striking the lower dorsal region. He had great pain at seat of injury. When picked up a few moments later, he was conscious and he stated that he could move both feet, although they felt numb. While being lifted into a wagon he received a severe jolt, and his legs at once became paralyzed. He was positive that the jolt caused the motor paralysis. He was taken to his home where I saw him the following day.

Operation.—A laminectomy, tenth and eleventh dorsal vertebræ, disclosed a complete destruction of the cord. Whether the laminæ were driven inward by the stone or by the jolt may be an open question. The laminæ, no doubt, were fractured by the stone, but it was probable that the dislocation of the laminæ was increased by the rough handling. The sharp fragments divided the cord. A curable patient was made incurable. After the torn fragments had been cut away, suturing with chromic gut was attempted but was not satisfactory, because the consistency of the cord was not firm enough to hold the suture. Wound closed as usual.

Result.—The patient died a week later.

CASE 13.—J. J. S., laborer, aged 27, was struck in the back of the neck by a falling tree, causing immediate paralysis, complete of legs, partial of arms.

Examination.—I saw him four days later. Tenderness was pronounced over the fifth and sixth cervical vertebræ. The skin was discolored at this point. The spines were movable.

Operation.—A laminectomy revealed a crushed cord to the extent of an inch. The wounds were treated in the usual manner.

Result.—Patient died ten days later.

CASE 14.—J. R., aged 28, clerk, was shot in the middorsal region, causing immediate motor and sensory paralysis from the costal arches down.

Operation.—Laminectomy of the fifth and sixth dorsal vertebræ. The cord had been cut by the bullet, which was deeply embedded in the vertebral body. The cord defect was cleansed from blood-clots and lacerated tissue. Wound closed.

Result.—The patient made an operative recovery, but died four months later from exhaustion and sepsis due to a very large bed sore on the sacrum.

CASE 15.—G. M., coal miner, aged 50. A mass of coal separated from the roof of a tunnel, falling on his back. When rescued by his co-laborers, it was found that his lower extremities had lost both motion and sensation.

Examination.—Two weeks later, when I saw him, paraplegia was complete. There was a distinct posterior angular deformity in the lower dorsal region over the tenth and eleventh vertebræ.

Operation.—Laminectomy disclosed fractured laminæ complete, laceration of the cord and crushed vertebral body, the tenth dorsal. It was not possible to correct the spinal deformity by either extention or pressure. The ragged cord ends were trimmed and the wound closed.

Result.—The patient died in four weeks, showing no improvement.

CASE 16.—D. S., farmer, aged 35, fell down a flight of stairs. He found it impossible to get up. After being put to bed, it was discovered that he had lost both motion and sensation.

Examination.—About one week later he was brought to the M. E. Hospital. He was found to be paraplegic. The fifth dorsal spine was movable, there was much pain in this region.

Operation.—Laminectomy. The fifth and sixth laminæ were removed, the meninges were contused. The latter were opened and the cord was found to be pulpefied. Wound closed in the usual manner.

Result.—Operative recovery was uneventful. He died from exhaustion and septic absorbtion from a large bed sore two months later.

SUMMARY

We had two cases with a contusion of the cord due to momentary pressure of one or two laminæ, where the spinal arch sprang back into place instantly, leaving no permanent cord destruction. One patient recovered both motion and sensation, walking out of the hospital in three months. The other was able to walk with the aid of a cane at the end of a year.

There was one case of compression in the presence of non-deforming fracture due to hemorrhage in the spinal canal. In one year he was able to walk fairly well with the aid of a cane.

Two patients were operated on in whom there was compression of the cord due to hemorrhage on and in the cord. One died one week after the operation, the other two months later with no improvement.

There was one case with paralysis due to compression of the laminæ of the sixth, seventh and eighth dorsal vertebræ without cord or meningeal injury. Recovery. This patient could walk with a cane in six months.

Four patients were operated on who had a partial destruction of the cord at the seat of injury. One improved so that he was able to stand on his feet after a year; there had been complete paralysis of all four extremities due to a fracture dislocation of fourth and fifth cervical vertebræ. Another patient died six weeks after a laminectomy of the seventh and eighth dorsal vertebræ. The third died ten weeks after the removal of the ninth and tenth dorsal vertebræ.

From the record of cases we note that no patient with complete transverse division of the cord was either temporarily or permanently benefited. All such patients died either from extreme trophic changes and exhaustion or from septic infection from the large bed sores.

ABSTRACT OF DISCUSSION

DR. H. W. HOWARD, Los Angeles: I shall not attempt to discuss this paper as a whole, but barely to emphasize the plea for early operation, believing that therein lies the only hope of relieving these poor unfortunates. It seems true that in the majority of cases in which the symptoms of severe injury of the cord have disappeared or greatly improved after operation, we are dealing rather with a compression than with total destruction of the cord. Still it has been proved beyond a doubt that regeneration of nerve fibers does take place in certain cases. There are many advocates for and against operative measures in these cases. When there is complete or partial paralysis and the extent of injury is very uncertain, I believe that operative procedures are necessary to clear up this point, also to give a chance to remedy the damage. One cannot say to what extent the cord has been injured until the dura has been opened. The external appearance of the dura frequently will lead one to believe that there has been no injury, or very slight injury to the cord itself, when on opening the dura one will find extensive injury.

Dr. Jonas has said that in most cases delayed operation holds no hope. I want to present a case here to illustrate that that is not always true.

The accident occurred in 1904 while the patient was diving in shallow water. It was followed immediately by paralysis, both motor and sensory, and semiconsciousness lasting two weeks; the consciousness then returned with partial or very slight sensation. Improvement was gradual for three months until he had very slight motion of the upper part of his arms only. Within a week this patient began to have bedsores, and in a short time his back was pretty well covered with them. After a year and a half some slight improvement began again, and for six months was rather marked. The bedsores healed up and he got more sensation and a little more motion. Paralysis of the sphincter muscles was complete, the patient having to be catheterized from the time of the accident until after operation. The bladder and kidneys became infected, and he was refused operation a number of times, being told that it was useless.

April 15 the patient presented himself to me, and a laminectomy was done.

The bodies of the vertebræ were found to be driven together, and there was overlapping of the laminæ. The laminæ of the fifth and sixth vertebræ were removed. The dura was found to be adherent to the laminæ and also to the vertebræ in front. The adhesions were broken up and the cord lifted to one side; the sharp projections from the bodies of the vertebræ were chiseled off, the cord replaced, the dura opened and found to be adherent to the cord for about 1½ inches. These adhesions were loosened, a probe passed up and down the canal to see whether there were further adhesions, which were found to be absent and the wound was closed.

The immediate effects of the operation were excellent. The heart steadied down; catheterization was found to be unnecessary after ten days; his bedsores healed, and in three weeks he had none; he began to use the intercostal muscles for breathing, and gradually returned to the use of the muscles of the arms and hands; the sphincter control of the bowels became normal, although at the present time he must take enemas on account of severe constipation.

In two months the patient was able to be propped up, feed himself with his hands, hold a newspaper, smoke a pipe, and was comparatively comfortable. He has improved steadily until at the present time he can move his legs. [Dr. Howard exhibited the patient.]

DR. STANLEY STILLMAN, San Francisco: My results in an operative experience of sixteen cases of fracture of the spine have been absolutely *nil*. The patients all recovered from the operation, but not one of them showed the slightest sign of improvement. The deformity in many of the cases was very slight. There was every reason to believe in some of them that improvement might be hoped for. Some of them lived for three years afterward, and one is now living six years since the fracture. The others died within three to six or eight months after the accident. The hope of regeneration after resection of a portion of the cord is of course absolutely futile. I have seen Sir Victor Horsley attempt to do such resection in an old case of fracture of the spine, encouraged by the "success" of an operation done in Philadelphia some years ago, in which it was claimed that regeneration of the cord had taken place after such resection and suturing of the damaged portion of the cord. But Dr. Murphy and others have shown us plainly that the nerve fibers not vested with a neurilemma are not capable of regeneration.

So that while I am not opposed in any way to operation, but, on the contrary, always give the patients and their friends the privilege of submitting to operation as offering the only possible chance of recovery, still it is done without any heart on my part, and without offer of probable benefit to the patient. In spite of the poor prognosis I think that operation is indicated, for it is certain that there are some cases, such as you have heard of here, in which pressure from hemorrhage, blood-clot or displaced fragments may be responsible for the paralysis, and in such cases recovery is possible. In fact, I have seen one patient recover without operation. The paralysis was not complete, and I did not operate on that account, and the patient recovered.

DR. C. P. THOMAS, Los Angeles: My experience has been about the same as that of Dr. Stillman. A number of cases have come under my observation in which I have operated with identically the same results. I believe that it is a well-established fact that regeneration of a severed cord by gunshot wounds or spinal fracture when immediate total paralysis follows, is irreparable; and regardless of what treatment we give these patients we get the same result—failure.

The patients that are relieved by operative procedure are doubtless those in whom the paralysis is due to pressure from hemorrhage; who would probably recover just as well without operation. I have seen a complete recovery after operation in a case in which hemorrhage was the cause; and I have also seen the same sort of paralysis follow injury to the spine—doubtless due to the same cause—recover without operation. So while with Dr. Stillman, Dr. Jonas and others, if the patient insists on it, and the family desire it, it has been my custom to do laminectomy. I always explain to them that it is my belief that the operation will not influence the recovery.

DR. D. C. STRONG, San Bernardino, Cal.: I want to thank Dr. Jonas for the attitude he has taken. The position taken by the greatest authorities almost precludes a man daring to operate in these cases. They speak as though the final word had been said on spinal-cord surgery, and that it only makes a bad matter worse to operate on a completely severed cord. This attitude has lessened the chances of many of these patients for recovery.

One year ago at the state society's meeting I reported and exhibited a case of complete severance of the cord, and a great deal of skepticism was expressed as to whether the cord had been completely severed or not. That was one of a series of four cases with which I have had to deal. In three of the cases practically no results were obtained. However, enough results in those three cases were obtained to lead me to believe that if properly handled we might expect a great deal more. These three patients all died from septicemia, the result of ascending infection; all three of them were suffering at the time of their injury from cystitis from specific infection. This one case which I reported was in a healthy, vigorous man, who was run over by a heavily laden wagon. The lower dorsal vertebra was fractured, completely severing the cord. The operation was done five days after the injury. The lacerated ends of the cord were trimmed off squarely and the cord united. The spinal nerve roots above and below the injury were approximated and united, taking care to preserve the ganglia, on account of the fact that the nutrient centers are in the ganglia and not in the cord. I believe it is due to the uniting of the nerves and the preservation of the ganglia that a large share of the function of the cord was maintained in this case. While the recovery was not complete, the man was able to stand, walk with the aid of crutches, and has apparently lost only the functions presided over by that portion of the cord actually destroyed. At present he is earning his own living.

DR. HARVEY CUSHING, Baltimore: Needless to say, only by a thorough preliminary neurologic study of these unfortunate patients can misinterpretations of the results of surgical measures be avoided. It is well for us surgeons to remember the pitfalls of the past, such as the reports of immediate restoration of function after suture of an injured peripheral nerve, a physiologic impossibility, of course, in the higher animals at least.

One may conveniently divide these cases into three groups. In the first operation is contra-indicated as spontaneous recovery is probable. The easily recognizable cases of hematomyelia are comprised in this first group; and the spinal palsies, accompanied by an acute flexion of the neck such as follow diving accidents, are often of this type.

Surgical measures are contra-indicated in a second group of cases, owing to the futility of intervention; and the mere fact that friends and patient desire it is not a sufficient defense or excuse for operation. These are cases of immediate total transverse lesion, after which a useful, if any, restoration of function at all is inconceivable. These cases are usually recognizable, if the patients are seen immediately after the injury, by the sharply cut, upper segmental level of total anesthesia and the complete abolition of the deep reflexes.

Now the third group of cases comprises those individuals with partial lesions from wounds or fractures in which prompt intervention is unquestionably indicated.

There are two points relating to the surgical treatment of these cases to which I should like to call attention. One concerns the care of the bladder, the other the method of entering the spinal canal. An immediate suprapubic cystotomy adds immensely to the comfort of these unfortunates and renders the liability of renal infection far less. In most of these patients the lower part of the trunk is without sensation, and it requires no anesthetic to make the very small suprapubic opening through which a retaining tube is introduced into the bladder. This obviates the dribbling which ultimately would occur, and favors the production of bed sores. It obviates, too, the irregularities of catheterization which must creep in in the best conducted surroundings. Urethral drainage by no means answers the same purpose.

Now as to the laminectomy. We must not forget that unless the laminectomy is delicately carried out the performance itself may do additional damage to the cord. Rough methods of exposure are much to be decried—methods of the mallet and chisel type. Adherence to such methods is what makes operators so often speak of the "shock" of laminectomies. Shock, so-called, arises from the trauma and loss of blood incidental to rough procedures. A laminectomy should be quite a bloodless performance and unattended by jar. It, in the first place, should be a median operation, hugging the spines and laminæ, from which the periosteum should be scraped away with care.

After removal of the spines the method of entering the canal which I employ is one which I can highly recommend to others. Primary entry down to the posterior ligaments is made with a Doyen perforator through the stump of each of the individual amputated spines—five or six, as the case may be, and rarely can a proper exposure be made with less. The perforator is followed by the burr which reams away each spine in turn and much of its adjoining laminæ. The lateral bony projections which remain can then be easily nibbled off with delicate sharp-nosed rongeurs, and a broad exposure of the canal is obtained.

The yellow, elastic posterior ligament is then delicately scraped away, down to the dura, and this membrane should be opened without injuring the arachnoid. This is an important matter and one, I believe, that is rarely observed. With the dura open and the bulging arachnoid uninjured the best possible view of the cord is obtained through the thin, delicate, transparent membrane, which will often enlarge the structures as though they were seen through a magnifying glass. I am sure that the emphasis which is laid on the loss of cerebrospinal fluid as an incident to "shock" is without foundation. A patient is so apt to be upset by rough methods of entry at this stage of the operation that the upset is attributed to evacuation of fluid, rather than to the preceding rough manipulations. In all cases, needless to say, the wound should be completely closed without drainage.

DR. A. F. JONAS, Omaha: Unfortunately we are not all highly trained neurologic surgeons, as Dr. Cushing is; and usually we get very little aid from the neurologists. Most of us who do general surgery have but a limited knowledge of neurology as affecting these particular injuries.

I have formulated this plan for my own guidance: in all cases of doubt, open the spinal canal. The opening of the spinal canal itself is not difficult or dangerous, and I am sure that in none of the cases in which I have operated have I made the patients worse. The wound itself heals well, and I have never had trouble with it. It seems to me for the average surgeon doing accident work, who has not had the advantages of neurologic training, such as Dr. Cushing has had, it is best to open the spinal canal and determine the exact nature of the injury.

It is true that all patients with transverse lesions of the cord have died sooner or later; but in partial cord lesions I have had one recovery, and that is the case of the fracture of the laminæ of the fourth and fifth cervical vertebræ, in which the meninges were torn and there was a considerable accumulation of blood, and the cord lesion was evident on examination. I admit there can be no regeneration of the cord when it has been transversely destroyed. It was impossible in my cases to bring the cord ends together and suture them, because the cord was so soft and inelastic, even when there was only a limited destruction of the cord elements.

The patients who recovered were those in whom there was a blood-clot in or under the dura, and the cord was not involved. They might have recovered anyway; but I could not tell positively before operation that there was no cord injury. So I opened them and did no damage.

The patients in whom there was hemorrhage in the cord itself, died; and so far as I have been able to learn from the reported cases, all such patients sooner or later die.

THE PRESSOR ACTION OF AN AMERICAN MISTLETOE *

ALBERT C. CRAWFORD, M.D.
PALO ALTO, CAL.

A certain mystic and poetic significance is attached to the term mistletoe because of the use of a European mistletoe (*Viscum album*) in the religious ceremonies of the Druids and in those of the early Christian church.[1] Norse mythology associated it with the worship of Freya, the Norse Venus, while Ovid and Virgil attributed magical powers to it. A species of mistletoe was collected with religious ceremonies by the Persian magi.

European mistletoe (*Viscum album*) has been used in medicine from very early times, its use being referred to by Paulus Ægineta,[2] Pliny, Dioscorides, Celsus,[3] and by the Moslem physicians Avicenna[4] and Ebn Barthar, although the conditions for its use have never been accurately defined. In the Middle Ages it had a high reputation in the treatment of nervous disorders.[5] In the seventeenth century interest was aroused by Boyle's note on the cure of epilepsy by it.[6] Recently Deguy[7] claimed that *Viscum album* was very serviceable in the treatment of albuminuria, and Delassus and Gaultier[8] have used it with some success in the treatment of tuberculous hemoptysis.

The gummy material obtained from this and other related plants has been used for the catching of singing birds, and, therefore, called "birdlime." *Viscum album* has been studied chemically by Grandeau and Bouton,[9] mainly with reference to its nutritive value. It has also been examined by Reinsch,[10] who isolated a crude product called viscin and a substance, viscautschin, resembling caoutchouc. Viscin yields viscinic acid and viscin oil. It is soluble in benzin, but insoluble in water. Viscin has usually been considered the active principle of *Viscum album*, although Reinsch, who first obtained this product, made no test of its physiologic activity. More recently Pavlevsky[11] obtained from *Viscum album* a crystalline acid by treatment of the plant with nitric acid, but nothing is definitely known of it. Crude viscin has been recommended as a coating for enteric pills, as a substitute for caoutchouc in the preparation of plasters and as a dressing base in cutaneous diseases.[12]

Muntz[13] obtained galactose by treating the gummy material with acid, and Tanret found both inactive and racemic inosit in *Viscum album*.[14] Others, as Knop,[15] Councler,[16] and Erdmann,[17] have studied the European mistletoe (*Viscum album*) with reference to its ash content. These analyses show a greater percentage of magnesium with reference to calcium than is the rule in plants. Recently Le Prince[18] obtained from this plant a volatile base having the empirical formula $C_8H_{11}N$. This compound gave the pyrrol reaction with a pine chip. Le Prince made no tests as to the activity of this base. He also reports the presence of a glucosid and resinous body, but details concerning the two latter bodies are not yet available.

This mistletoe has been used in certain parts of France as an addition to the food of stock,[19] but its value remains to be determined. According to Heim, dogs fed with this plant show scarcely any symptoms.

The common mistletoe of the eastern part of the United States is *Phoradendron flavescens*.[20] It is at times popularly called "golden bough."[21] This plant is often confused by medical writers with *Viscum album*. Both plants are parasitic to various trees.[22] Laurent has suggested that the European species secretes a principle which is poisonous to its host.[23] In this country various species of mistletoe are causing considerable damage to trees and work is now being done to obviate this destruction.[24]

Some years ago interest was reawakened in the *Phoradendron flavescens* by the announcement that marked oxytocic powers could be attributed to it. It was claimed that it was active even when ergot failed.[25] This plant has been used to produce abortion by the negroes of the southern states, and also by the Indians of Mendocino County, California.[26] It was also once supposed to be useful as an aid to fecundity. The Kaffirs of South Africa believe their species of mistletoe to affect the secretion of the kidneys.[27] The Chimariko Indians of California are said to smoke an oak mistletoe as a substitute for tobacco,[28] while certain of the Arizona Indians use the *Phoradendron juniperinum* as a substitute for coffee.[29] Both the *Viscum album* and the *Phoradendron flavescens* are claimed to have the same medical action and have been used as substitutes for digitalis in cardiac therapy;[30] but perhaps this belief has arisen by the confusion of the two species. The Orientals, however, consider the mistletoe injurious to the heart.[31] Payne[32] studied the action of the fluid extract of *Phoradendron flavescens* on various lower animals, but failed to control these injections with a corresponding amount of alcohol, and his data were insufficient to justify any conclusions.

Both the European and American species are claimed at times to produce poisoning. The symptoms reported have been those of vomiting and purging, and collapse;[33] hallucinations and bounding pulse, stertorous respiration, rigid and dilated pupils. Certain of the Indians,[26] however, assert that it is merely mistletoes grown on certain trees which are poisonous, and Cornevin questions if the European species is really poisonous.[34]

The American plant has practically fallen into disuse as a medicine, but now considerable attention is being directed to the study of the European species. Some years ago I noted that if an aqueous or a fluid extract of American mistletoe (*Phoradendron flavescens*) was injected into the cardiac end of the saphenous vein of a narcotized dog, whose vagi nerves had been cut, there followed a temporary fall in blood-pressure, but this was succeeded by a sharp rise associated with a rapid heart-beat; this rise in the systemic blood-pressure was very persistent. If the vagi were not cut the rise was more gradual, and if atropin had been previously used, the injection of mistletoe caused no initial fall in such animals. But while the rise in blood-pressure resembled qualitatively that produced by epinephrin, extracts of mistletoe when applied to the conjunctiva failed to produce local vasoconstriction. Accompanying this rise of blood-pressure was an immediate increase of urinary secretion. This increase in urinary secretion could be determined by counting the drops as they fell from ureteral cannulæ. A short notice of this find appeared,[35] but this investigation has been sidetracked by other work.

Of the plants known as mistletoe in our western states, three were examined: *Razoumofskya americana*, *Phoradendron juniperinum*, and *Phoradendron villosum*.[36] Of these *Phoradendron juniperinum* alone seemed to give the characteristic rise in blood-pressure.

In the case of the European species of mistletoe, *Viscum album,* Gaultier[37] found that the injection of extracts of this plant into the cardiac end of the vein of a dog, whose vagi were intact, was followed by acceleration of the heart-beat with a lowering of blood-pressure. Chevalier[38] traced this hypotensor action of mistletoe to saponin-like glucosids, but he did not isolate these bodies. Gaultier apparently makes no mention of any rise in blood-pressure, but he noted an increase in the urinary secretion. Doyon and Gaultier[39] have recently claimed that this extract interferes temporarily with the coagulability of the blood.

CHEMICAL EXPERIMENTS

The leaves and twigs of the *Phoradendron flavescens* were first used, but later it was found more convenient to start with the fluidextract of mistletoe such as is found on the market. All fresh fluid or aqueous extracts of the fresh *Phoradendron flavescens,* which were examined, produced this action, but some old ones were almost inactive. The fluid extract of mistletoe was bought from two of the large drug manufacturing firms of the country, in both of which botanical identifications are made. By starting with the fluidextract, the method of isolation of the active principle could thus be shortened.

At first lead acetate was used to precipitate various inert bodies. It was noted that, in removing the lead from the filtrate by hydrogen sulphid, the solutions lost their activity if this gas was passed into aqueous extracts of the plant, but not in the case of strong alcoholic solutions. As the use of lead did not simplify the problem, it was soon given up.

One hundred c.c. of the fluidextract of mistletoe were evaporated *in vacuo* to free from alcohol and the residue was then taken up in a little water. This solution (about 20 c.c.) was poured into a bottle of about 2 liters capacity and a quantity of ether poured on the fluid, and calcined magnesium oxid was gradually added in sufficient quantity to take up the water and free any base present. The bottle was shaken, preferably in a shaker, for about one hour, and filtered after five or six hours standing. Three such shakings extract practically all the ether-soluble pressor compounds. There was, however, some reason to believe that perhaps the mother fluid still contained a pressor body not shaken out by the ether. The ether, which had an amin odor, was filtered into a pear-shaped separatory funnel and a drop of concentrated hydrochloric acid added with a stirring rod. If there was merely a trace of water in the ether, clumps of beautiful crystalline needles would separate on the walls of the vessel. These crystals produced the intense and persistent rise in blood-pressure characteristic of the original extract. The amount of crystals obtained by means of hydrochloric acid was small and the yield was very uncertain, perhaps owing to the hygroscopic character of the hydrochlorid. The salt melted at about 250 C.

It was found that if, in place of hydrochloric acid, an ethereal solution of oxalic acid was used, a crystalline compound could be more easily obtained. On reprecipitation, these crystalline needles were usually perfectly white, although at times a third precipitation was necessary to remove all color.[40] If ordinary U. S. P. ether was used, these crystals gave an ash residue, but if the ether used for the extraction was first shaken with water to remove alcohol, and then distilled over calcium chlorid and sodium, the crystals obtained by this second shaking were practically ash-free and melted between 187-190 C. The oxalate was optically inactive. Some of the compound was apt to be lost in the second shaking with magnesium oxid and ether, so to avoid this only a minimum amount of water was used for solution and at first only small quantities of magnesium oxid were added, then the ether shaken vigorously and more magnesium oxid added, so as to take up all the water. Some experience is required to obtain a satisfactory yield.

Again, in isolating the base from the first oxalate, it was found necessary to use the purified ether, as the ordinary U. S. P. ether "shaking" yielded only a few crystals. The ethereal solution of the free base gave no precipitate with an ethereal solution of iodin, or of picric acid, or with carbonic acid, and the oxalate gave no precipitate with platinum chlorid. However, a platinum compound was obtained from the hydrochlorid.

On evaporating the ethereal solution of the base, freed from the colorless oxalate, a colored gummy material was left and this gave a colored solution with water, suggesting that the free base readily underwent oxydation.

Before analysis, the oxalate was shaken vigorously three times with anhydrous ether, so as to remove any attached oxalic acid and then the crystals were dried *in vacuo* over sulphuric acid. Of one sample of the second oxalate 0.1612 gm. were mixed with copper oxid and burnt. This amount yielded 0.3194 gm. CO_2 and 0.0858 gm. of H_2O, or C—54 per cent., H=5.95 per cent.

Of one lot made by precipitating three times with oxalic acid 0.0951 gm. gave 0.1889 gm. of CO_2 and 0.0549 gm. of H_2O, or C=54.1 per cent., H=6.4 per cent.

By the Dumas method and mixed with cuprous chlorid, 0.1504 gm. of one sample of the second oxalate gave 9.3 c.c. N at 21.8 C. and under 765.8 mm. barometric pressure, so that N=7.03 per cent., while .155 gm. of the second lot gave 9.75 c.c. N at 22 C. and under 763 mm. barometric pressure, therefore, N=7.15 per cent.

This would correspond to C 54 per cent., H 6.2, and N 7.09 per cent. The simplest percentage formula which would answer this requirement is $C_9H_{13}NO_4$. This would correspond to 4 oxygen atoms, so that only one oxalic acid group can be present. If we subtract the oxalic acid group, it would leave us $C_7H_{11}N$ as the probable formula. Hass[41] has shown that certain carbon compounds, when burnt by the copper-oxid method, do not yield the theoretical amount of CO_2, as some of the carbon passes off unabsorbed as methane. Under these circumstances the formula $C_7H_{11}N$ must be considered merely as provisional, at least until an analysis of the platinum-double salt can be made.

Barger and Dale[42] have recently shown that most of the activity of ergot is due to various amin bodies, primarily p-hydroxy-phenylethylamin, and Barger and Walpole have found that phenylethylamin is present in ergot in small quantities. This has been shown by Dale[43] to cause an epinephrin-like rise in blood-pressure. This rise resembles that obtained from the mistletoe base. Phenylethylamin has a percentage formula $C_8H_{11}N$.

As the mistletoe base gives the isonitrile reaction with caustic potash and chloroform a primary amin was indicated. These facts would suggest that perhaps the active principle might in reality be phenylethylamin, and that the carbon determinations were a trifle low, but phenylethylamin (Kahlbaum), when dissolved in ether and precipitated with oxalic acid, gave a body with C 64.6 per cent., H 7.3 per cent., and melted at 218 C. This would correspond to phenylethylamin monoxalate $[(C_8H_{11}N)_2C_2H_2O_4]$, and not to the dioxalate $(C_8H_{11}N.C_2H_2O_4)$. The monoxalate demands 65 per cent. C and 7.5 per cent. H. Benzylamin was first suspected to be the pressor principle, but its oxalate $(C_7H_9N\ C_2H_2O_4)$ melts at 175 C., that is, over 12° C. lower than the mistletoe oxalate. The fact that my analysis of the monoxalate of phenylethylamin by the copper oxid method gave a slightly lower percentage than the theoretical amount of carbon, would suggest that, perhaps, my carbon determinations are a trifle low and that the real percentage formula may prove to have the percentage composition $C_8H_{11}N$. So that at present, the data at hand is not sufficient to identify the active pressor principles of our southern mistletoes. Further chemical work will be done on this subject and the therapeutic possibilities discussed. The question whether this compound retains its activity when given by mouth with be investigated.

ABSTRACT OF DISCUSSION

Dr. Reid Hunt, Washington, D. C.: Do you consider the diuresis to be due to a direct effect on the kidney, or to result from the change in blood-pressure?

Dr. A. C. Crawford, Stanford University, Cal.: I have gone carefully over the early literature on ergot and have never seen any statement that there was a diuretic action associated with its use. I have not as yet analyzed physiologically the action of the mistletoe, but suspect that its diuretic action is secondary to that on the circulation; but cannot prove this at present.

HISTOLOGIC EXAMINATION OF THE FAUCIAL TONSILS WITH REFERENCE TO TUBERCULOSIS *

E. C. SEWALL, M.D.
Associate Professor of Ophthalmology, Laryngology and Otology, Cooper Medical College
SAN FRANCISCO

The question of the relationship between the tonsils and tuberculosis is one that has been agitating the minds of pathologists and clinicians since Trautman in 1886 called attention to the possible connection.

It was not till 1895 that laboratory methods were brought to bear by Dieulafoy, who performed inoculation experiments on guinea-pigs and made the startling announcement that out of ninety-six pigs inoculated with bits of tonsil, fifteen showed tuberculosis. Later research has shown that these figures are not reliable.

The work has developed by rapid stages. Goodale in 1896 proved that minute particles of carmin could be absorbed quickly by the tonsil. Although bacteria are not so easily absorbed we have abundant proof that such absorption does take place. Dmochowitz and Wood have reported seeing the bacteria in the act of penetrating the tonsil.

The frequency of the presence of tubercle bacilli in the mouth varies enormously. In individuals in the later stages of tuberculosis of the lungs it has been shown that myriads of tubercle bacilli pass the tonsil in the sputum. Also the respired air carries tubercle germs in proportion to their presence in the atmosphere. Oral respiration favors infection from inspired air. It has been shown that air that has passed through the nasal cavities is remarkably free from bacteria. The next point that was conclusively shown is epoch-making in importance; it is that tubercle bacilli can be absorbed into the tonsils. All that is necessary is an ample dosage of sufficient virulence, without an injury to the tonsillar mucous membrane being necessary. Wood, in 1905, by experiments on hogs, which have considerable tonsillar tissue, was able to infect the tonsils and cause the formation in them of tubercles by simply swabbing on their surface virulent cultures of tubercle bacilli.

In this connection, the percentage of tonsils showing tubercles in patients suffering from tuberculosis is most interesting because we have in them the same conditions as in Dr. Wood's experiments. The percentage of such tonsils showing tubercles is so high that some men have even gone so far as to say that in all cases of tuberculosis of the lungs coming to autopsy the tonsils show tubercles.

It has thus been established fairly conclusively, by experimentation and actual pathologic observation, that the tonsils become infected with tubercle bacilli and that typical tubercles form within them. The infecting germs may be coming from within the body, in which case we have secondary tuberculosis of the tonsil, or they may enter the mouth with food or otherwise and find primary lodgment in the tonsil.

While it is conceded that tuberculosis of the tonsils is, as a rule, secondary to tuberculosis of the lung, and that primary infection of the tonsil is comparatively rare, a great deal of material has been collected in which diagnosis of primary tuberculosis of the tonsil has been made. The number of cases runs between 1,600 and 2,000 and the abundant material in the hands of different observers gives a percentage a little over 5. These figures are fairly well agreed on. The diagnosis in these cases has rested on inoculation experiments and histologic findings.

The next question is, What are the clinical earmarks by which we can look into the mouth and diagnose such an infected tonsil? Speaking as I am in this paper altogether of non-ulcerative processes, I might say that there are no signs by which the condition can be recognized. Some men have described particular features, but the majority of observers agree that there are no distinguishing signs. Danziger, for one, reports the careful examination of 100 tuberculous patients. A certain large percentage of such patients are said to have tuberculous tonsils. Danziger could recognize no points on which to make a diagnosis. When the course of infection is once followed into the tonsil, how much farther is it possible for the tuberculous progress to be traced?

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911

It has been proved that the lymph from the tonsil drains first into the superficial glands of the neck, and then into deep glands. The first gland of the chain, Wood has called the tonsillar gland; it is situated near the angle of the jaw. It is usually the first to enlarge in tonsillar trouble and when pushed outward by underlying, swollen glands, may be mistaken for the submaxillary salivary gland. The passage of the tubercle bacilli from the tonsil to these glands has been shown experimentally by Wood. Not only were tubercles found in the tonsil after the swabbing of the hogs' throats with virulent tuberculous culture, but within a comparatively short time the corresponding cervical glands were involved. Not only was he able to show that the glands were involved simultaneously with the tonsils, but also that the glands could be involved and show tubercles without the tonsil, which had been swabbed, becoming involved. In other words, the bacilli passed through the tonsil without leaving any trace. Others have shown that the passage of tubercle bacilli and other germs through the intact mucous membrane of the intestine is quickly accomplished. Tuberculosis thus enters the system in doubtless many cases. Bacteria can also be made to pass through the intact mucous membrane of the mouth, but with difficulty.

The absorption is much slower than that from the tonsil, as shown by the infrequency of the cervical gland enlargement in inoculated guinea-pigs, which have little or no tonsillar tissue.

From the above citations the infection of tonsils and lymph-glands of the neck has been clearly established. The cause of cervical tuberculous adenitis in the great majority of cases is clear. What is the danger of general or pulmonary tuberculosis from tubercle bacilli entering by this path?

Grober has done some painstaking work and, as a result, contends that there is direct connection through the subclavian glands and by contiguity, with the pleura and apices of the lungs. In 1900 he believed he could trace particles of India ink from the tonsils to the apices.

Beitzke has criticized Grober's conclusions and summarized his own results thus: 1. There exist no lymph-vessels leading from the chain of cervical lymphatic glands to the bronchial glands. 2. Infection of the lung could take place only through the lymphatic trunk and veins. 3. This path is not of importance in children. The infection of the lungs and hence the bronchial glands as a rule takes place through aspiration.

Wood says the danger of systemic pulmonic infection resulting from a tuberculous lesion of the tonsillar tissue is about equal to that from tuberculosis of the cervical lymphatics. The lesion to be expected from the broken down glands of the neck is a miliary tuberculosis of the lungs. Further than this possibility, tuberculosis of the lymph-glands of the neck is no more dangerous than localized tuberculous lesion in any other portion of the body. It must be borne in mind, however, that the cervical glands are those most frequently involved, being affected in about 90 per cent. of the cases of lymph-node enlargement. The frequency of enlargement of these particular glands is noteworthy in the light of the experimental findings cited.

It would appear from the foregoing paragraphs that the etiology of tuberculous glands of the neck had been fairly established, but as many of our texts and best reference works govern medical opinion and action, a few quotations from them will show that there is need of all additional statistics possible on this subject. It was with the object of adding a little to these statistics that the work was undertaken at Cooper Medical College and this paper is presented.

Osler in his "System of the Practice of Medicine" says: "Much has been written of late on the relation of the tonsil to tuberculosis, especially with regard to the importance as a portal of entry; but even now, after the study of hundreds of cases, there is no great unanimity of opinion."

Keene's "System of Surgery," speaking of operative treatment of tuberculous glands, says: "Some patients are relieved of all symptoms of tuberculosis and gain rapidly in health. A considerable number fail to obtain a complete cure and succumb ultimately to pulmonary or to another form of tuberculosis.

Demmé found in a report of the Berne Hospital that in 29 per cent. of 692 cases of cervical tuberculous adenitis observed, the patient died of tuberculosis. This book does not mention the removal of the tonsils, which were the probable cause of the glandular condition. Is there any wonder that the glands go on enlarging and becoming tuberculous as long as one remains to *protect* the individual?

It is a fact that many of our general surgeons remove what glands they can in tuberculous cervical adenitis and will reoperate one or more times without removing the tonsil in its entirety.

Since 1907, 1,088 pairs of tonsils have been enucleated in our private practice or in the ear, nose and throat clinic at Cooper Medical College. Of these, 772 pairs have been examined in the pathologic laboratory of the institution by Professor Ophüls and Assistant Professors Dickson and Oliver. This represents the sectioning of 1,544 individual tonsils and this material is equal numerically to about half of all the cases that have heretofore been gathered from the literature.

The method of examination has been to harden the tonsils for twelve hours in Orth's fluid and then make a few frozen sections from the middle of the tonsil. Where it seems advisable from the general appearance of the tissues, these are followed up in some cases by a few more sections. These additional sections are made in different axes. The tuberculous condition, when present, is quickly recognized and typical tubercles, as described in the original communication of Koch, are made the basis of the diagnosis. Most of the articles that have been published have gone into detail as to the great sources of error in the diagnosis of tonsillar tuberculosis until one is driven to the conclusion that absolute diagnosis is impossible. At the same time Wood, for example, and in fact all others, have accepted in their statistics cases where the diagnosis has rested on the histologic findings.

It is said that to establish a diagnosis of tuberculosis of the tonsil it is necessary (1) to demonstrate the tubercle histologically, (2) to find in it the tubercle bacilli and (3) to prove that they are tubercle bacilli and not some acid-fast impostor, by inoculation of animals which shall show at death tuberculosis. True, these are the laws laid down for the recognition of tuberculous lesion, but do we apply them in this hard and fast manner in diagnosing, histologically, tuberculosis of kidney, liver, lung or other organ?

Such evidence is certainly not required to establish the diagnosis of tuberculosis in other parts. The tubercles are identical whether they occur in kidney, spleen, liver, or tonsil, and inoculation of animals is required only when the typical tubercle cannot be found. The bacilli are not found in a very large percentage of cases where absolute and unquestioned diagnosis is made. Why, then, has there been so much question about the diagnosis of the tuberculous lesion in the tonsil? A tubercle in the tonsil must be differentiated from the round, light germinal area, but to the experienced eye there is no difficulty in so doing; there is no caseation in such an area.

The next point that investigators insist on is the presence of giant cells in the tubercle to establish its tuberculous character. Giant cells are fused epithelioid cells and are often found in the tonsil in tuberculosis, but it is certainly possible to make a diagnosis of tuberculosis from the tubercle without demonstrating their presence. Then it is said, even when we do find giant cells, that they may be caused by foreign substances. True, such giant cells may occur, but even then the picture to the experienced pathologist is not tuberculous.

I wish to add also that in the 1,544 tonsils examined not one such "foreign body giant cell" was found, and if it had been found, in all probability the foreign body would have been demonstrable.

In regard to the greater value of inoculation experiments, I should say that where performed on the tonsil they have not the same value as when performed on other tissues, because we cannot possibly free the tonsil, by washing or other means, from all tubercle bacilli that may be lurking in the crypts or elsewhere, and the use of the center of it might miss the tuberculous portion.

The quasi-inert character of the tubercles, and the difficulty in finding tubercle bacilli in them, would suggest that the resistance of the guinea-pig might be sufficient to withstand the few bacteria evidently present.

The presence, as we have seen, in tonsils of cavities containing from a few to 15 or 20 minims of creamy pus, adds to the difficulty of this method of diagnosis, for this pus would surely lead to acute peritonitis, if injected into the peritoneal cavity of a guinea-pig.

The finding of the bacilli, practically impossible with the means and time at hand, is open to the objection that acid-fast bacteria, though extremely rare in such a connection, may creep into our calculations.

It seems to me then that the histologic examination of the entire tonsil, the sections numerous enough to include every tubercle, is the only diagnostic method not open to criticism.

The work of the laboratory of Cooper Medical College has been histologic, but it has been subject to error due to the few sections made. Tuberculosis has been reported in thirty cases out of the 772.

A very thorough piece of work has been done by Dr. Downing, assistant in the clinic, in an endeavor to check up the laboratory findings and determine the percentage of error.

Dr. Downing examined a series of twenty pairs of tonsils which had been previously passed upon by the laboratory as free from tuberculosis. They were blocked in paraffin and sections stained about every 0.1 mm. throughout the entire tonsil. "This was considered amply sufficient to gain a section of any microscopic tubercle that might exist. Dr. Walsh of Baltimore, in studying the frequency of tuberculosis of the kidney, considered it sufficient to make only from three to 120 sections from the two entire kidneys."

Downing stained the sections in hematoxylin and eosin. The twenty pairs of tonsils examined gave from 100 to 216 sections to the pair. The average number was about 100, making a series of over 2,000 sections. In this series, Dr. Downing found one tuberculous tonsil that was overlooked by the pathologic laboratory routine. In this case 100 sections were made. Twelve of these showed definite tubercles with giant cells of the Langhans type. Dr. Boardman, working along similar lines, examined twenty-three tonsils already examined by the laboratory and found no tubercles present.

To sum up the work, there have been 772 pairs of tonsils examined by the pathologic laboratory routine under Professor Ophüls and Professors Dickson and Oliver. Thirty-eight of these sections, representing thirty pairs of tonsils, were pronounced tuberculous. That gives a percentage of tuberculous tonsils of 3.9.

The work of Drs. Downing and Boardman in examining a control of forty-three pairs with *one* tuberculous adds about 2.3 per cent. to the findings, making the percentage of tuberculosis in the tonsils 6.2.

The next question is, What has a study of the material afforded as to the influence of the infected tonsils on the cervical glands? We received communications from, or saw personally, 160 patients who had been operated on during the five years. Sixty-eight of these patients had enlarged glands, varying from slight enlargement, of probably benign character, to extreme tuberculous condition with softening, fistulas, etc. Of these sixty-eight cases, the glands subsided in fifty-seven cases and have not enlarged again.

In three of these fifty-seven cases the glands and tonsils were both tuberculous; the first was diagnosed by an examination of the tonsil and some of the glands which were removed prior to the tonsillectomy; the second was diagnosed from the presence of a cold abscess, opened at the operation on the tonsils, the third from the character of the very considerable swelling which subsided immediately on the removal of the tuberculous tonsil.

This leaves eleven of the sixty-eight cases with enlarged glands to be considered.

1. In six cases, glands, enlarged before the operation, went down, but subsequently enlarged. Have a complete record of only four of these six cases. In the first case the tonsils were not tuberculous. The patient was operated on later in the surgical clinic; the glands were quiet for one year and then enlarged again.

In the second case the tonsils were tuberculous and fluctuating glands were opened at the time of tonsillectomy. They have since enlarged frequently.

In the third case the tonsils were not tuberculous; the glands were undoubtedly tuberculous. They went down slowly after the operation till six months later; then they swelled and a painless abscess formed that was opened. This healed, and the patient's health at present is good.

In the fourth case the tonsils were tuberculous; the glands were enlarged before operation, but went down slightly some months later. Suppuration occurred; they were removed and showed histologically tubercles. The present condition is good.

2. In two cases the glands were enlarged before and did not go down at operation.

In the first of these cases the tonsils were not tuberculous; the glands remained swollen after operating; have never broken down.

In the second case the tonsils were tuberculous. Tonsillectomy had no effect on the swelling of the glands. The glands were removed in a surgical clinic six weeks later. At present the cervical glands are still enlarged.

3. Three cases, in which there was slight enlargement before, present the same picture. The tonsils in these cases were not tuberculous.

To summarize 160 cases:

Ninety-two had no enlarged glands.

Sixty-eight had more or less enlarged glands.

Fifty-seven of these went down permanently.

Six went down and enlargement recurred.

Two which were enlarged before operation did not subside.

Three were slightly enlarged and are now.

1. It will be seen from the above records that quite a large percentage of the children had enlarged glands, but many of these were only slightly swollen.

2. Practically all of the glands giving trouble have been associated with tuberculous tonsils, or were tuberculous at the time of the removal of the tonsils.

3. That the removal of the tonsils worked in a beneficent manner is shown by the fact that often the swollen tuberculous glands subsided, though not always permanently.

4. That certain tuberculous glands are not associated with tuberculous tonsils is of especial interest. We believe that tubercle bacilli can travel to the glands without damage to the tonsil, and this accounts for the following facts (also for the higher percentage of tuberculous glands):

5. Glands once tuberculous, associated with tuberculous tonsils or not, may enlarge even after the tonsils have been removed.

6. We find tuberculous glands more often than we find tuberculous tonsils.

7. Even when there is a reappearance of the swelling, the glands show more of a tendency to heal and the individual to enjoy health after the tonsils have been removed.

In closing, I wish to call attention to a most noteworthy group of cases occurring in one family. They were referred to me by Professor Oliver, who made the pathologic examination of the tonsils and glands.

In the first case a girl aged 4 had much enlarged tonsils. There was no glandular enlargement of importance. The tonsils were removed and found to be tuberculous. The patient has been well since, with no enlargement of the glands. She has had diphtheria since. Her present condition is good.

In the second case a girl aged six had considerably enlarged glands. The tonsils were removed and showed definite tuberculosis; the glands later suppurated and were removed; they showed definite tubercles. The patient has had diphtheria since. Her present condition is good.

In the third case a baby aged 6 months had enlarged tonsils, but no glandular enlargement. The tonsils were removed and showed definite tubercles. The child had diphtheria one year later and following this succumbed to pneumonia. A grandmother living in the house had tuberculous laryngitis and the mother has fistula in ano.

The tonsils in these cases were quite large. A number of observers have said that tuberculosis is found more often in the small tonsil. We have found that to be the case in the majority of instances, but certainly not in all. One patient, for instance, had one large and one small tonsil. The larger was the tuberculous tonsil corresponding to the much-enlarged glands; the other was free from tuberculosis.

Perhaps the most significant point brought out by this paper is the fact that out of the 160 cases reported, though there were sixty-eight cases with enlarged glands, fifty-seven of which went down, there was not a single case in which there was enlargement of the cervical glands subsequent to the removal of the tonsils, except in those few (eleven) cases in which the glands were already enlarged at the time of the tonsillectomy.

135 Stockton Street.

ABSTRACT OF DISCUSSION

Dr. F. P. Emerson, Boston: In an adenitis which is far advanced it would seem that the primary source of the trouble was in the tonsil and that the tonsil should be removed radically. Sometimes the glands are enlarged by toxemia and will go down if the primary focus is removed. If the tonsil is tuberculous there may be a subsequent enlargement of the gland that will require its removal later. But we should go on record as being opposed to the indiscriminate removal of the tonsil. In the East the reaction has not taken place and we are radically removing all of these tonsils. If they are tuberculous there is no question about their removal. If they contain a focus of infection we should remove them. But we should encourage the profession to require a reason for removal of the tonsil. The general practitioner is assuming to dictate to the specialist what to do. He will direct the patient to go to Dr. So-and-So, who will remove the tonsil by the new method, which is with the capsule intact. But I think in every case the question whether the tonsil should be removed should be kept in our hands and we should have the courage of our convictions and say, if the tonsil is enlarged only through hyperemia, that it need not come out necessarily, especially in a child, say, under 7 years of age.

REPORT OF PRIMARY INFECTION OF BULB SINUS AND JUGULAR IN A WOMAN OF FIFTY-SIX*

SHERMAN VOORHEES, M.D.
ELMIRA, N. Y.

History.—April 10, 1909, Mrs. H., a woman aged 56, was admitted to the surgical ward of the Arnot-Ogden Hospital. The patient said she had been in poor health for two months past but had kept to her work, which was that of a forewoman in a knitting mill. Two weeks prior to her admission to the hospital, I was asked by her physician to see her in consultation at her home, as she had been ill of influenza for about a week and was having severe pain in the right ear. On examining the ear I found a small perforation in the lower posterior quadrant through which some pus was flowing. The upper part of the drum was highly inflamed and bulging. Under local anesthesia I incised this freely and left the after-care of the patient to her physician. I did not see her again until she was sent in on my service at the hospital.

Examination.—On examining the ear I found a very free discharge and a good opening in the membrana tympani, which seemed adequate for the escape of pus. The patient told me that she had constant pain and the discharge had been very profuse. She complained that the pain was deep in the ear, and pressure over the tragus caused acute suffering. There was no tenderness over the mastoid or sagging of the wall of the canal, and no enlargement of lymphatics about the neck, although she complained that the pain sometimes radiated down to the clavicle. Her temperature on admission was 102.2 F. at 11 a. m., pulse 100, respiration 24. At 6 p. m., same day, the temperature reached 104.2 F., pulse 104 and respiration 28. Under sponging and free catharsis it dropped to 99.4 F. A culture showed streptococci in the discharge and a leukocyte count of 9,200, with 85 per cent. polynuclear.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Treatment and Course of Disease.—The ear was irrigated with mercuric chlorid solution at three-hour intervals, and as the patient complained of aching, I prescribed for her sodium salicylate. She seemed very septic; the tongue was heavily coated, with sordes on the teeth, the breath foul. She kept complaining of the severe pain deep in the ear. Her temperature was taken at two-hour intervals for the next three days and ran between 99 and 103 F. There was but little tenderness down the neck, although she complained of pain at this spot at times. The leukocyte count showed 11,000, with about the same polynuclear percentage. She had a chill, and at 9 p. m. on the fifth day her temperature reached 105, and the pain in the ear and down the neck was intensified. I decided then to operate, as I felt sure we had a primary involvement of the sinus and perhaps of the jugular also.

Operation.—I opened the mastoid, which contained no pus, but all the cells seemed greatly congested and bled freely as they were broken down. On reaching the bone overlying the lateral sinus, this was found perfectly healthy and gave no evidence of disease underneath. This was chiseled away rapidly and the sinus was found to be very dark and pulsated and seemed soggy to the touch. I uncovered this vessel well toward the torcula and nearly to the bulb, and had on completion of the dissection a large vessel bulging into the bony wound. I made a long incision into the sinus, but except for some oozing from around the clot there was no hemorrhage. On removing the thrombus from above, hemorrhage was quickly established, but removing the plug from below and using the curette gently, did not establish hemorrhage from that source. I then prepared the neck and opening it along the anterior sternocleidomastoid border and opening the carotid sheath found the thrombus extending well down the vein. I ligated the vein close to the clavicle and high up in the neck. All its branches were thrombosed and these were carefully dissected out, together with the vein. Hemorrhage was established from above on removal of the ligature, probably from the inferior petrosal. The wound was cleansed and a cigarette drain inserted, and the patient sent to the ward.

Postoperative History and Treatment.—The morning following, the temperature was 97.8 F., and the pulse 94; the temperature remained normal until the end of the second day when it rose to 101.4 F. and kept gradually rising until it reached 103.2. The wound was dressed and seemed to be doing finely. The thrombus having shown streptococci, I gave the patient antistreptococcic serum. In a few hours the temperature dropped to 99.4 F., but by the end of the following day had reached 103.2 F. in the axilla, pulse 120, when I again gave another injection of the serum. At this time the patient became very restless and was delirious, the breath foul, sordes on the teeth and a badly furred tongue and the lips were cracked and sore. The urine up to this time had shown no evidence of kidney or bladder disease, but blood was noticed in the urine voided. The patient, when conscious, complained of pain in the right hip and radiating down the thigh and leg. On examination a large indurated area was found over the right hip which was very tender to touch but there were no points of softening. This thrombic area grew much more extensive and more hemorrhage occurred. Pus was present also in the urine and showed large numbers of streptococci. The patient was profoundly septic and only conscious part of the time. Control of bladder and bowels was soon lost and diarrhea supervened. The temperature ran between 102.4 and 104 F. and pulse 90 to 130, together with all symptoms of sepsis, and death took place on the nineteenth day after operation.

I do not believe that had I tied off the vein prior to opening the sinus it would have made any difference in the outcome, but think the woman had thrombus on admission and should have had early operation with tying off the vein first. The case is of interest on account of her age as it is rare to find primary thrombus at this time of life, and unusual also to have metastatic thrombus into the bladder.

408 North Main Street.

ABSTRACT OF DISCUSSION

Dr. J. F. Barnhill, Indianapolis: When a patient is violently taken, as was this one of Dr. Voorhees, with the discharge of a large amount of pus, it is certain that the pus is not coming solely from the middle ear, but from all the cavities leading into the ear. When we see such large quantities of pus or of serum, it almost certainly means an extension to the middle ear and its associated cavities. Dr. Voorhees was wise in sending the patient to the hospital, for it is difficult to make the diagnosis of intracranial complications in the home, unless one makes a hospital of the home. The diagnosis often escapes us because we are unable to get all the facts in the case, and unless a competent nurse is constantly present to observe and record them. Dr. Voorhees does not mention any chill or vomiting. Undoubtedly he would not have operated so early if he had not obtained so much help in the diagnosis. The affection of the bladder is a unique feature of the case. I have frequently seen affection of the limbs with abscesses. I have within a year had a case of sinus thrombosis complicated by a large abscess of the knee, in which the patient recovered. But the early diagnosis is very important in these cases.

Dr. W. E. Sauer, St. Louis, Mo.: Some of the members will remember the patient I presented before the Section at St. Louis last year. He had never had a discharge from the ear at any time. The case was referred to me by a neurologist, who had been called in by the general practitioner. Th patient had had no chill up to that time. The only thin which led us to suspect a phlebitis was the pain on pressur along the jugular. The patient was perfectly rational an gave no history of ear trouble. I did a paracentesis br nothing was found. An oculist was called in and some cor gestion of the disk was found. The next day he had a chi with a temperature of 103 F.; we operated and found th sinus filled with pus. There was an ultimate recovery.

Dr. P. Schoonmaker, New York: A case came under m care at the New York Post-Graduate Hospital on Dec. 30, 191 which this report brings to my mind. A German, aged 2 with a history of otitis media purulenta chronica since childhood; left ear healed when 10 years old; right ear continued to discharge until the time he presented himself at the hospital with a history of chills, fever, headache, pain and tenderness over the mastoid for three or four days. He presented septic appearance, demanding immediate operation. This wa done at once. Mastoid large, and external table sclerotic cavity large; pneumatic cells necrotic and filled with foul smelling pus and formative growth. The middle ear was i the same condition. I removed this and all necrotic bone uncovering the dura and sinus over a large area. The sinu was thrombosed, necrotic and collapsed on cross-section, discharging pus. I was unable to remove the clot from th sinus and secure free bleeding. The patient was in a collapsed condition. Saline transfusion and stimulation wer employed. The operation was stopped, the wound cleansed and dressed and the patient put to bed. There was a sever chill six hours later. Dec. 31, 1910, the pulse was 100, temperature 97 F., blood examination showed 30,400 white cell with 90 per cent. polynuclear cells. Patient was very septic body edematous; wound cleaned and dressed. Jan. 1, 1911 a second chill followed by high temperatures; jugular vei resected; sinus cleaned, obtaining free bleeding from torcula end; sinus packed; pus seen coming from dura behind sinus opening enlarged and about 2 ounces of pus evacuated from brain abscess; cavity cleaned and packed with iodoform gauze; wound dressed daily. The patient improved for three days. On the sixth day bleeding occurred from the nose which the house surgeon took to be an epistaxis and packed the nares. Death occurred a few hours later. Autopsy showed that the packing had been pushed out of the sinus and that the hemorrhage had come from the sinus through the Eustachian tube, causing death.

Dr. M. D. Stevenson, Akron, Ohio: I would like to cal attention to the importance attached to the microscopic examination of aural discharges in the New York Eye and Ear Infirmary. I learned last winter, from the bacteriologist there, and from Dr. Dench, that the presence in the discharge of the *Streptococcus mucosus capsulatus* is considered sufficient to justify early operation. The patient may have little or no pain, little fever, no increased polymorphonuclear count and very little, if any, leukocytosis, and yet if this germ is present there is likely to be early involvement of the sinus. After returning home I had my assistant examine the discharge more commonly than before and we discovered only one case. In that case the patient refused the operation suggested, but later I heard he had to have two operations performed. There were practically no other symptoms when I saw him, except the discharge.

Dr. Sherman Voorhees, Elmira, N. Y.: This was a primary infection of the bulb, undoubtedly, although I did not find any opening into the bulb. As the last speaker said, I am satisfied that the case came from infection of the bulb. There was absolutely no pus in the mastoid. Except for the cells being congested, there was no affection of the mastoid. I was, unfortunately, denied an autopsy. The diagnosis was made from the high temperature and the sudden drop. When we get a temperature of 105 to 106 F. I think we are justified in exploring to see if the sinus is not thrombosed. The infection must have come from the middle ear.

A CASE OF MYOSITIS OSSIFICANS PROGRESSIVA

ARTHUR R. ELLIOTT, M.D.
CHICAGO

The opportunity of recording the history of this patient I owe to the courtesy of Dr. Lucian D. Clark of Toledo, Ohio, who brought her to me for examination December 7, 1907.

History.—The patient, F. B., was a girl of 17. There had been *no other case of myositis ossificans in the family.* Both parents were of American birth, living and in good health; no lues, no tuberculosis; two other children were living and in good health, neither of them presenting any developmental anomalies. Birth of patient was non-instrumental and labor was *neither prolonged nor difficult.* She was breast-fed and did not suffer from any infantile diseases nor exanthemata. At the age of 1 year it was first noticed that the thumbs and great toes were malformed. The mother stated that shortly after the patient entered her second year lumps (nodes) were observed to form on the head. They were never due to injury and appeared and disappeared without apparent cause. They were tender to pressure but never suppurated. At intervals during the succeeding three years similar nodosities developed on the back and shoulders, coming and going, but never entirely absent. At the age of five torticollis appeared and persisted about six months, the muscles of the neck being hard and tender. Subsequently swellings appeared on the arms and legs, interfering greatly with voluntary movements, so that the patient could neither feed herself nor walk. These swellings were painful and tender and more or less ephemeral, shifting from place to place on the extremities, lumps or nodes showing from time to time on the back. These were very sore but never suppurated. Since the age of 5 the patient had never been able to freely abduct the arms and had never in her life been able to comb her hair. When she was about 5 years old her medical attendant discovered the existence of a valvular heart lesion. There had been no previous definite rheumatic or other acute infection. The general health had never been robust, but aside from the special disabilities of her disease there was an entire absence in her history of morbid incident until January, 1907, when she had typhoid fever. In July, 1907, Dr. Clark was consulted for stiffness of the jaws. The jaws were locked so that she was unable to masticate solid food and was compelled to subsist entirely on a liquid diet. The teeth could be separated but very slightly, the submaxillary region being filled with a hard bony deposit. Shortly after this development swellings were observed along both sides of the thorax. These were hard and circumscribed but were not tender to pressure or painful, and were apparently not connected with the ribs. These gradually disappeared. In October, 1907, the arms became stiff and the right elbow joint developed a partial fibrous ankylosis, preventing voluntary movements of the joint and but slight manipulative freedom of the articulation. The right elbow remained uninvolved and freely movable. Gradually the left shoulder became stiff, movements of the left arm on the body being seriously restricted.

There had been little pain throughout, the only subjective discomfort being a certain soreness and tenderness on pressure and manipulation of the indurated areas during the early stage of their formation. The skin over involved areas had at times been suffused and slightly edematous. As the indurations grew harder the soreness would disappear and when fully developed no tenderness was present.

Areas of involvement had been observed to disappear and there had been periods of arrest or quiescence during the progress of the disease. Soon or late, however, fresh areas of induration would make their appearance and run through a subacute progress to firm bony consistency causing much *interference with muscular function.* Repeated involvement of the same muscular area had taken place with final persistent hardness. There had been slight pyrexia at times. The patient's general health had always been unsatisfactory and her activities seriously compromised. Menses were regular since the twelfth year and somewhat profuse. There had been frequent epistaxis.

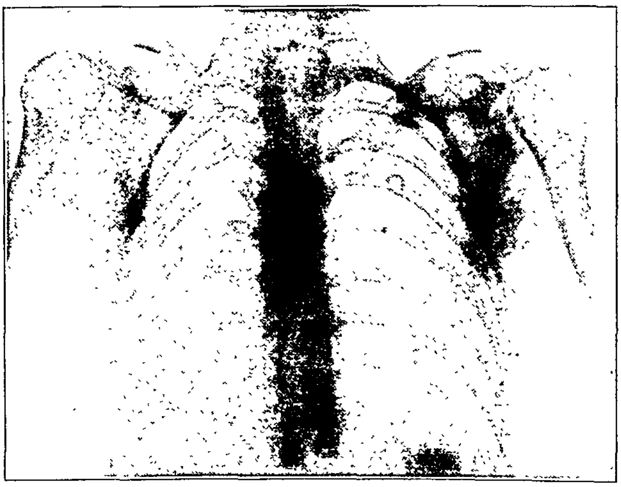

Fig. 1.—Bony induration of the submaxillary tissues; the lower jaw was displaced to one side and the incisor teeth did not articulate. The anterior and posterior muscles of the neck presented more or less induration; the mastoid end of the sterno-mastoid muscle was bony; a hard, insensitive node is shown on the superior border of the left scapular spine and small bony exostoses on the eighth, ninth and eleventh ribs near their posterior angles. A rod-shaped bony mass can be seen lying diagonally in the left pectoral region.

General Physical Examination.—The patient's stature was small, her face pale and round, her hair fine in texture and moderately abundant. The first point of interest to be remarked was the posture. The shoulders were rounded, the normal dorsal curve of the spine being increased. The head was bent forward, the chin flexed on the chest and there was but slight passive or voluntary mobility, either lateral or vertical, of the head. There was no hardness or induration of the masseters or other of the facial muscles. There were no cranial nodes. The teeth were well formed, even, with good enamel. The gums were soft and spongy at the teeth borders, bleeding easily, so that a tooth-brush could not be used. Maxillary movement was much restricted, so that it was possible to separate the teeth about an inch only, and the lower jaw was displaced from left to right so that the incisors did not approximate accurately. This restriction of movement and deformity was due to the presence of bony induration of the submaxillary tissues (Fig. 1). This mass was smoothly continuous with the jaw, reaching around to either angle. The overlying skin was soft and normal in appearance. Swallowing was not interfered with. The thyroid could not be palpated. The muscles of the neck, both anterior and posterior, present more or less firm induration, the mastoid end of the sternocleidomastoid being of bony consistency, while the clavicular insertions of the muscles stood out prominently and were firm but not bony. No glandular enlargements were present. A hard non-sensitive node was felt on the superior border of the left scapular spine. There were small bony exostoses on the eighth and eleventh right ribs and ninth left rib near their posterior angles and also on the crest of the ilium at the left sacral angle. The last was slightly tender to pressure. The body was bowed somewhat forward and rotation of the trunk or head was impossible. The patient could not pick objects off the floor. There was no scoliosis but the spine was rigid. When the patient was lying down, by placing a hand behind the head one could raise the trunk as if the whole spine were a rigid rod. A broad bony mass lying on either side of the lumbar and lower dorsal spine could be felt as if the erector spinæ muscles were turned to bone. This induration formed two parallel planks with a combined transverse diameter of 10 cm. and reached from the sacro-iliac border up well into the dorsal region (Fig. 2). These bony plates were slightly movable and seesawed when pressed on at either end. A very interesting development was apparent in the abdominal muscles of the right inguinal region, where a mass of firm induration about the size of the palm of a hand could be felt. This was of recent origin and was tender to pressure, the overlying skin being suffused and somewhat hyperesthetic. The pectoral muscles were hard and contracted, the arms being locked to the sides so that abduction was impossible. A distinct hard mass could be made out in the body of the left pectoral group (Fig. 1). This mass appears in the *x*-ray picture as a rod of bone, clubbed at both ends, lying in the long axis of the muscle and resembling in shape a child's femur. The biceps of both arms were indurated; no mobility of the shoulder-joints was possible. The deltoids and triceps appeared atrophied. The patient stated that but a few weeks before the arm muscles were much more swollen and hard than at the time of examination. The right elbow-joint was fixed in a position of slight flexion. This was apparently due more to muscular than to intra-articular changes (Fig. 3). A peculiar malformation of the right ulnar head existed. The ulna was about an inch shorter than the radius, to which it was attached by a bridge of bone (Fig. 4). A somewhat similar deformity was noted by Hutchinson[1] in one of his cases. Deformities of both thumbs existed. These consisted of complete bony ankylosis of the terminal phalangeal joints, the second joints being pliable but atrophied and dry (Fig. 5). There had never been any voluntary movement of the thumbs, which were held in a position of flexion on the palms. The thenar eminences were flat and atrophied. The muscles of the legs were much freer from involvement than the trunk and arm muscles, but the patient stated that they felt too short and often became sore and tender. There was some restriction of movement of the hips, knees and ankle-joints. Congenital deformity of both great toes existed. This consisted in the absence of one phalanx, the toes being short and directed outward, lying partly under the second toes, giving the appearance of hallux valgus.

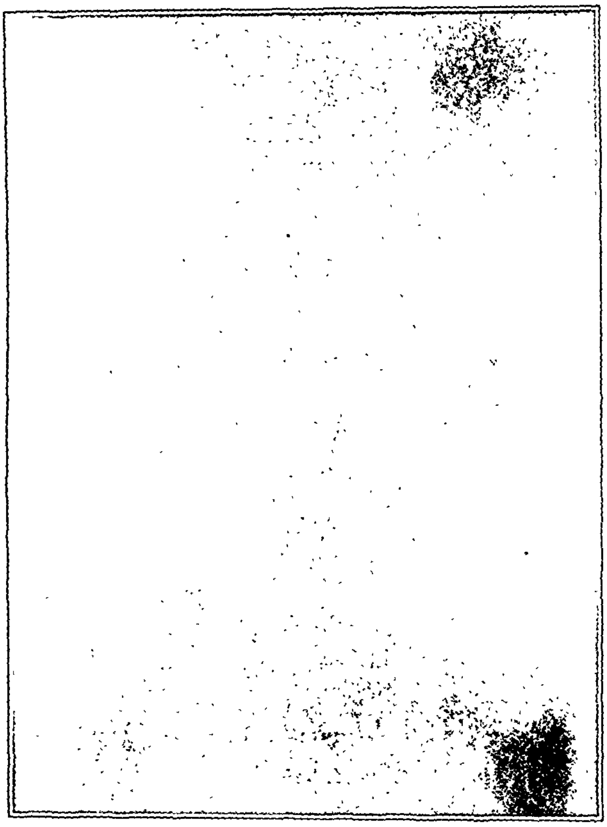

Fig. 2.—The spine was rigid. Broad bony masses are seen on either side of the lumbar and lower dorsal spine, as if the erector spinæ muscles were turned to bone, forming two parallel planks with a combined transerse diameter of 10 cm. They were slightly *movable.*

Visceral Conditions.—The skin was dry but not harsh, nipples deeply pigmented, mammæ undeveloped, no general panniculus. Lungs: Examination negative, respiration largely diaphragmatic owing to fixation of the thorax. Pulse 90, regular; temperature normal. Heart: Apex 12 cm. from midsternum; there was a well-marked systolic thrill and the double systolic murmur of aortic stenosis and mitral regurgitation.

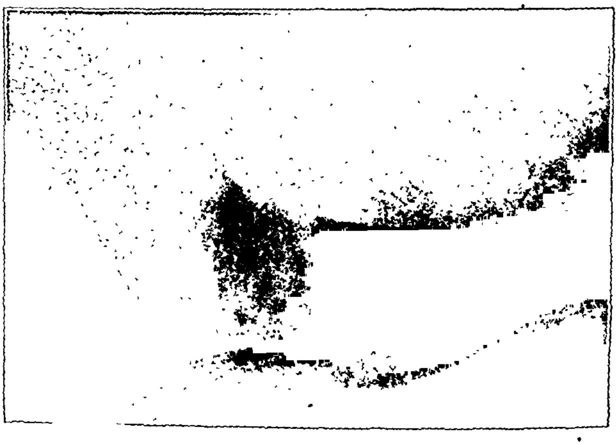

Fig. 3.—Showing the right elbow-joint fixed in a position of slight flexion and a peculiar malformation of the right ulnar head.

Abdominal examination was negative; no splenic or hepatic enlargement. A good view of the throat was impossible, owing to jaw-lock; throat smear showed pneumococci and staphylococci.

Leukorrhea present; vaginal examination not permitted and no smear could be obtained.

Blood Examination.—Specific gravity 1.054, erythrocytes, 4:420,000; Hgb., 75 per cent.; leukocytes, 10.800. Differential count: lymphocytes, 23 per cent.; large mononuclears and transitionals, 5 per cent.; neutrophils, 70 per cent.; eosinophils, 2 per cent.

Blood-Cultures: Two flasks of bouillon, one containing 2 c.c. blood and one 4 c.c., placed in an incubator at 37 C. for seventy-two hours showed no growth of organisms.

---

[1] Hutchinson: Arch. Surg., vii, 1896.

Urine.—Quantity in twenty-four hours, 900 c.c. Sp. gr., 1.020; albumin, minimal trace; sugar, absent; indican, pathologic excess; urea, 20 gm.; uric acid, 0.653 gm. *pro mille;* sediment, cells, cylindroids, oxalates and urates: no casts.

Course of Disease.—The patient was not again seen until February 19. Her condition at that date was as follows: The induration of the biceps and arm muscles had very considerably diminished. The hardness and tenderness in the abdominal muscles previously noted had almost entirely disappeared, leaving only a small, circumscribed, insensitive area of firmness in the right inguinal region. Since last consultation a large sensitive node had formed on the left scapular spine, but this was undergoing resolution. This appearance of sensitive indurated areas and their subsequent gradual disappearance characterized the progress of the case from the beginning. For a fortnight previous to the last consultation there was a slight daily rise of temperature of about 2 degrees Fahrenheit at its maximum. Recent advices from Dr. Clark convey the information that during the two years that have elapsed since my last examination of the patient her condition has undergone no particular change.

The foregoing clinical history is reported because of the great rarity of cases of myositis ossificans progressiva and the interest attaching to its etiology. Since Freke's[2] first clinical report of this disease in 1740, his description, corresponding very closely with that now given, only 107 cases, including the one herewith described, are recorded in medical annals. Doubtless many more examples of the disease have been observed, but have not been made matters of record. For a full consideration of the subject those who may be interested are referred to Münchmayer's[3] classic description of the disease and to excellent monographs by Pincus,[4] Roth,[5] Helferich,[6] and DeWitt.[7] DeWitt's articles furnishes a review of the literature down to the year 1900, adding eleven collected cases to the sixty-seven already gathered by Pincus and Roth, making a total of seventy-eight cases to that date. Walker,[8] in 1908, taking up the records where DeWitt left off, added fourteen reported cases, bringing the total to ninety-two. Since that date thirteen new examples,[9] including the present report, have been placed on record and I have found in the literature four other case histories[10] that have been overlooked in the reviews mentioned, making the grand total 107 cases to January, 1911. But nine of these have been reported from America.

Progressive ossifying myositis is not to be confused with the less rare forms of local ossifying myositis following traumatism and inflammation. Many cases are on record of ossification of single muscles or groups of muscles, sometimes following a single severe trauma, in other cases resulting from repeated injury or prolonged irritation. Under this last head may be included the ossification of the deltoid and arm muscles of soldiers and the thigh muscles of riders. Mention should be made also of calcification occurring in the course of chronic inflammatory processes which may be rheumatic, tuberculous or syphilitic, or due to foreign bodies lodged in the tissues. Myositis ossificans progressiva is distinguished from any of these localized forms by the fact that it commences spontaneously in early life and progressively advances until the muscular system is extensively involved. A further distinguishing feature, if one were needed, is the occurrence in the great majority of these cases of congenital malformation and defect which shall be presently described.

Most of the recorded cases of myositis ossificans progressiva can be traced back to early childhood, the majority beginning before the tenth year. Owing to the masked character of the symptoms during its early stage it is often impossible to fix the exact date of its origin. The earliest signs of ossification reported occurred at 4 days after birth, at 3 months, 8 months (Wilkinson), and 3 months (Horand). Cases have been noted as beginning at a later period of life. Thus Kroneker relates the case of a woman in whom the disease began at 54.

Although of slow development and prolonged course the disease advances along definite lines to a uniform termination. This fact alone would suffice to establish the disease as a pathologic unit. The course of its development is about as follows:

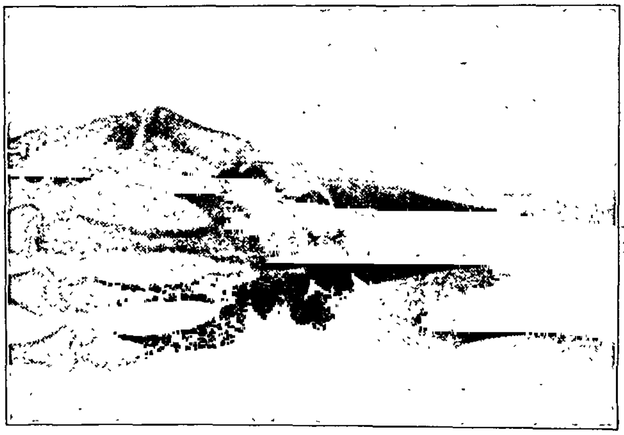

Fig. 4.—The right ulna presents a peculiar malformation, being about one inch short and being attached to the radius by a bridge of bone.

A child otherwise in good health develops a local swelling of tender character in some part of the muscular system, usually the neck, producing a condition which may be mistaken for torticollis, or the back or shoulder, pectoral or abdominal groups of muscles may be first affected. The involved area is indurated and may be the seat of local and radiating pains, and the overlying skin is not infrequently suffused and sensitive. After a period of several weeks, during which the local symptoms slowly abate, the swelling may disappear, leaving the muscle more or less indurated, a condition which is sometimes temporary but may remain permanent. A series of recurring attacks of myositis may affect the same area, finally producing a bony hardness of the muscle. During the course of years successive localizations of this character occur until a condition of deplorable deformity and crippling results. The joints may become fixed and greatly restricted in pliability, not by true ankylosis, but by the rigid bars of bone formed in the substance of the muscles acting on them. In this manner deflections of the spinal column, flexions and rotations of limbs occur. From pressure and irritation the overlying skin and cellular tissues may slough, forming ulcers and exposing the patients to septic accidents. In Linden's case the discharge contained gritty particles of bone and small sequestra. Sometimes large, deep abscesses are met with, doubtless due to irritation set up by sharp spiculæ of bone (Rogers, Stoneham).

The distribution of the changes in the muscles is almost always the same, the trunk, upper extremities and neck being the seats of involvement. Rarely do bony plates appear in the legs, and the hands and feet are always exempt. The ossification of the muscles of the neck has caused the disease to be mistaken for torticollis and suboccipital Pott's disease. Of the facial muscles the masseters alone have been involved, this constituting a grave development by interfering with alimentation. A very frequent accompaniment or precursor of the myositis is the appearance of exostoses. These are most frequently seen where the long bones approach the surface; i. e., the anterior surface of the tibia, the ribs, the skull, etc.

One of the most striking and peculiar features of this interesting disease is its association with certain congenital deformities. This point was first noted by Gerber, but Helferich[6] emphasized the association as a chief characteristic of the disease, and since then 75 per cent. of cases reported have shown the peculiar congenital malformations. These consist of microdactylia, a shortening of the great toes and thumbs, and, more rarely, the little fingers, due to a dwarfing of the metatarsal and metacarpal bones, with subsequent ankylosis of the interphalangeal joints. This gave the false impression before the *x*-ray was used that one phalanx was absent. The great toes are often directed outward and frequently lie under the second toes, giving rise to the deformity of hallux valgus. Other less frequent malformations are absence of certain muscles, absence of lobules of the ears, absence of superior incisor teeth, atrophy of testicles, and mammæ, and sexual infantilism. It is interesting to note that deformities of the hands and feet were observed in the father of Sympson's[11] patient, although he did not develop the disease.

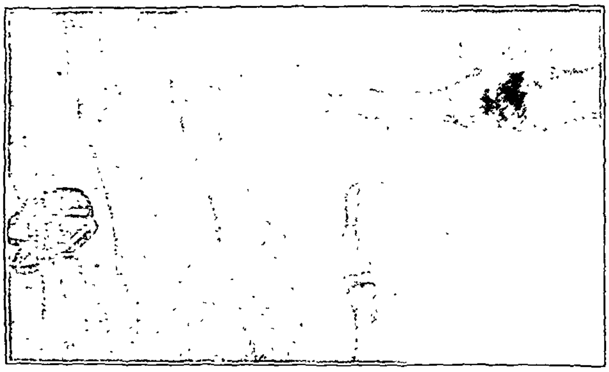

Fig. 5.—The thumbs were fixed in a position of flexion on the palms of the hands and could not be voluntarily moved. The terminal phalangeal articulation of right thumb has undergone bony ankylosis.

Myositis ossificans progressiva is essentially a chronic disease, subject, however, to exacerbations. An exception to this rule is noted by Ferraton,[12] who observed a patient who was able to eat in a perfectly normal manner on going to bed, but on rising in the morning found it impossible to open the mouth owing to involvement of the masseters, and at the same time noticed a hard tumefaction in the right masseter. The usual history of the disease is a slow progression with longer or shorter pauses, the general health as a rule remaining good until increasing disabilities interfere with feeding and respiration, or on account of the latter disturbance some pulmonary infection develops. The average duration of the disease is from ten to fifteen years.

The clinical course of every case observed leaves no doubt that myositis ossificans progressiva is an inflammation—a progressive polymyositis—terminating eventually in certain of the involved areas in ossification. In the case just reported I had the good fortune to observe an acute involvement of a very definite character in the parietal abdominal muscles. There were present all the signs of an ordinary acute myositis. Three months afterward, all indications had disappeared, the former involved area appearing normal in all respects. It is a matter of record that indurated areas that have existed for some time have undergone resorption, to the surprise of the observers. Although there is little to distinguish the individual lesion in its earlier course from an ordinary myositis, the disease becomes stamped with a special character when its course is followed for any period of time. A striking feature is its association with exostoses of the skull, ribs, scapular spines and ilia, which furnish proof of a tendency to aberrant bone formation, this later being further exemplified by the depositions of bone in the affected muscles. The congenital developmental defects constitute a very interesting feature, as they would appear to indicate the operation of a predisposing factor of congenital origin. The sequence of histologic changes through which the soft tissues pass to bone have been repeatedly observed and are exactly similar to those described in myositis ossificans traumatica. From the periphery to the center of the implicated area a sequence of fibrotic changes are apparent, passing through fibrocartilaginous transformation to osteoid trabeculation and calcification. New connective tissue, cartilage, osteoid tissue and bone are found in the same section. The new formed osseous plates possess the same histologic and chemical characters as does true bone.

Many theories have been advanced to explain the etiology of this extraordinary disease, but with little success at solving the problem. The disease cannot be classed with other conditions in which bone formation is observed as a terminal development, such as calcification in degenerated arteries, about old foci of tuberculosis, around foreign bodies, etc. These are but instances of the metaplasia of connective tissue and as such have eventuated in new formation of bone in nearly every tissue and organ of the body. The lesions of myositis ossificans are confined to the skeletal layer of the mesoblast. The visceral layer is never affected. There is no direct heredity. The only instance on record of occurrence in two generations of the same family is a case reported by Burton Fanning.[10] The father of Fanning's patient had suffered from myositis ossificans progressiva, dying at 33 from an accident.

No exciting cause but injury has been established as the starting point of the disease. In a few instances injury has certainly produced local ossification and proved the apparent inception of the disease. In four of thirty-eight cases collected by Pincus the onset is plausibly ascribed to injury. The site of the lesions in most cases is, however, opposed to this idea and in the overwhelming majority of cases no such explanation can be entertained. There is no doubt, however, that after the disease is well under way traumata that in normal individuals would produce no such result are followed by myositis and ossification. It is interesting to note at this point that research into calcium metabolism undertaken by Austin[13] on one of Painter's patients showed a perfectly normal calcium metabolism.

[12] Ferraton: Rev. d'Orthop., 1903, Series 2, iv, 302.

Without entering into details regarding the many theories that have been advanced, it may be mentioned that it has been thought to be a form of rheumatism (Stoneham), a trophoneurosis (Nicholadoni, Eichorst, etc.), a new growth (Mays, Zeigler), a form of atavism (Brennsohn), while Hutchinson claims it to be a morbid tissue perversion analogous to retinitis pigmentosa and xeroderma pigmentosum. None of these theories meets with acceptance, the present trend of opinion being toward the view that owing to some disposing factor of congenital origin—indicated by so large a percentage of microdactylia and exostoses—the muscles seem to be endowed with very low resisting power and are consequently highly susceptible to inflammation from various exciting causes which ordinarily would not so operate, such as injury, chemical and bacterial irritants, etc. Combined with this low resisting power of the muscles there is a morbid disposition to aberrant bone growth which shows itself in the calcification and ossification of inflammatory products.

Herringham, in sympathy with Pincus, finds many points of resemblance to multiple fibromata, namely, multiplicity, limitation to certain mesoblastic areas, and benignity. They are both also congenital, increasing by gradually attacking fresh areas, but always growing from one tract of tissue, never involving any other by continuity or metastasis. The chief stumbling-block to acceptance of this idea is the existence of congenital deformities found in 75 per cent. of cases. These mark the disease as peculiar, and it is difficult to connect them with new growth. In this extraordinary disease we appear to be on the borderland between malformation and new growth.

I gratefully acknowledge my indebtedness to Dr. R. W. Webster for assistance in reviewing the literature.

FIBROMA OF NOSE

W. J. COLLINS, M.D., AND J. D. COLLINS, M.D.
NORTHAMPTON, MASS.

History.—The patient, H. B., aged 72, American teamster, had no remarkable family history. He had grip and severe pneumonia sixteen years ago; otherwise his personal history was negative. He admitted very free use of gin for thirty-eight years, but since 1905 he had taken not more than two drinks each month (?). About fifteen years ago he noticed a small red spot under the skin on the right side of the nose. The redness increased gradually until it covered the whole nose; then he noticed it was beginning to enlarge. The growth was very slow and gave him no inconvenience, except the appearance, until one month before he was seen. About this time he had dragging pain over the eyes, dizziness, frontal headache and when leaning over to lift boxes, etc., he would lose his balance and fall. These symptoms led him to seek relief. Previous to this time he had many strange ideas, that he ought not to part with the tumor, that he would bleed to death or die in some other way if it was operated on.

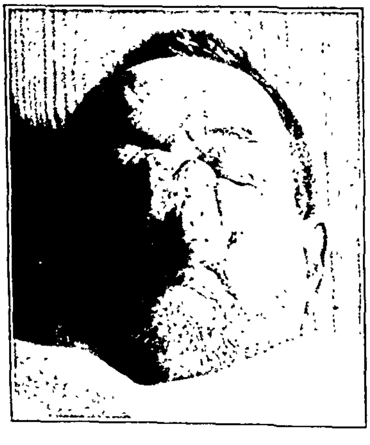

Fig. 1.—Front view of fibroma of nose.

Physical Examination.—The patient proved to be a remarkably strong healthy man, although 72 years of age. A lobulated mass 7.5 cm. lateral and 5 cm. vertical, was found firmly adherent to the lower three-fourths of the nose. It was somewhat larger and more dependent on the left and obstructed the field of vision, except upward and outward. It was firm to the touch and could be lifted away from the mouth, which it almost completely covered. Figures 1 and 2 make further description unnecessary.

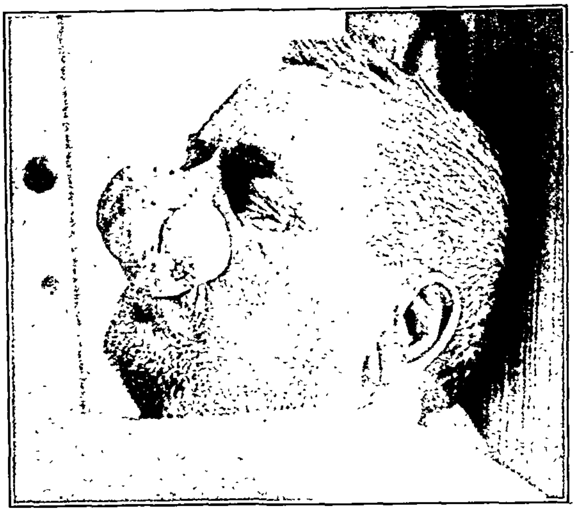

Fig. 2.—Side view of fibroma of nose.

Operation.—Under ether the growth was removed, an especially sharp scalpel being used. The rough and irregular tissue was shaved down to correspond to his normal nose, but in spite of much care, the right adherent ala was partly removed. The bleeding was very profuse but controlled by pressure and cautery. Four weeks were required for healing, and the patient would not allow skin-grafting to cover in the lower part of the left ala. Macroscopically, it was thought to be a fibroma—the end-result of an acne rosacea—and the microscope confirmed this diagnosis.

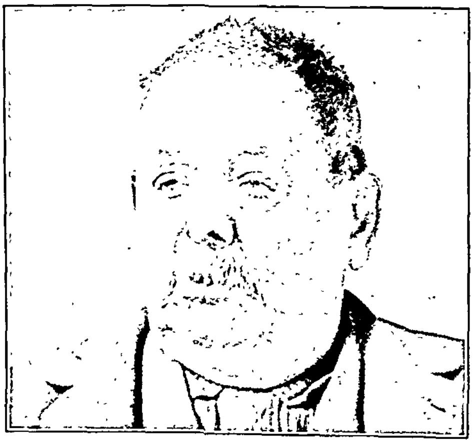

Fig. 3.—Same patient after removal of fibroma of nose.

SURGERY OF EXPERIMENTAL LESION OF SPINAL CORD EQUIVALENT TO CRUSH INJURY OF FRACTURE DISLOCATION OF SPINAL COLUMN

A PRELIMINARY REPORT *

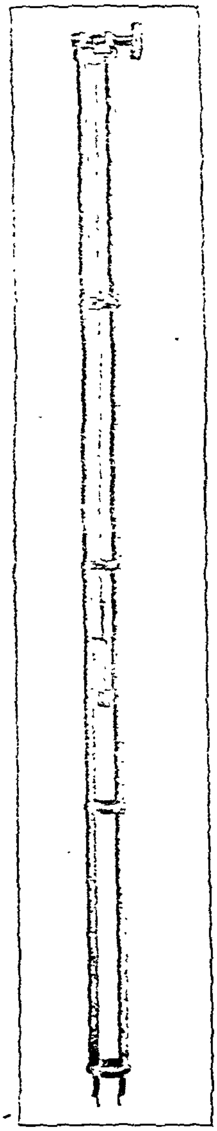
ALFRED REGINALD ALLEN, M.D.
PHILADELPHIA

PREFATORY REMARKS

In two former papers I have dwelt at length on the mechanical considerations of injury to the spinal cord in cases of fracture dislocation of the spinal column.[1, 2]

In this communication, therefore, I shall limit myself to the discussion of the experimental work in which I have been engaged for the past year in the laboratories of the University of Pennsylvania.

I would accentuate the fact that this is a preliminary report and that I am fully aware of the amount of control experimentation necessary before an *ex cathedra* statement can be made as to applicability of this work in the human subject.



Instrument for producing a measured impact on the spinal cord.

MEASUREMENT OF IMPACT ON SPINAL CORD IN SPINAL FRACTURE DISLOCATION

In order to arrive at an adequate concept as to the amount of impact a spinal cord could receive and yet recover its function, I designed an instrument whereby a given weight could be dropped from a known height thereby producing a given impact (see the accompanying illustration).

A dog having been thoroughly anesthetized, a laminectomy is performed, the instrument placed in position and the weight dropped on the spinal cord. The resulting impact in gram-centimeters is the product of the height in centimeters and the weight in grams. The element of friction in the instrument is so inconsiderable that it may be regarded a negligible quantity.

HYPO-IMPACT AND HYPERIMPACT

In my work I have used dogs varying in weight from 7.5 kilos to 18 kilos. The laminectomy has been performed in the lower third of the thoracic region.

I have found that a weight of 30 gm. may be dropped on the spinal cord from a height not exceeding 11.5 cm. with every expectation of an uninterrupted recovery on the part of the animal. The resultant of 339 gram-centimeters is one wholly in accord with complete autorestoration.

So soon as we exceed an impact of 340 gram-centimeters (to speak in round numbers) we obtain symptom pictures of more serious import.

Whereas an impact of 340 gram-centimeters will produce a complete paraplegia of spastic type, which, in course of a week or ten days, will have largely disappeared, so soon as we begin to use impacts of greater magnitude, we find the symptoms more severe and more lasting. Most animals injured by a 420 gram-centimeter impact will present a serious symptom picture; complete spastic paraplegia with scissor-like crossing of the hind limbs, emaciation, paralysis of the bladder and rectum and trophic lesions. An impact of 450 gram-centimeters will produce a symptom picture of complete transverse lesion of the spinal cord and the animal will die in the asthenic and toxic state so familiar to all who have had experience with fracture dislocation of the spinal column in the human subject.

I therefore term all impact below 340 gram-centimeters "hypo-impact," and all impact above this amount "hyperimpact."

THE HYPOTHESIS OF SYMPTOM-COMPLEX OF TRANSVERSE LESION OF THE SPINAL CORD IN FRACTURE DISLOCATION OF THE SPINAL COLUMN

Without restating *in extenso* the views concerning pressure on the cord from fragments of bone or the intramedullary pressure of hemorrhage or edema, with which views I have dealt in previous articles, I would say that I consider it a very uncommon occurrence to find a passive impingement of bone on the spinal cord when the operation of laminectomy is performed for fracture dislocation.

We must assume one of two theories, or probably both, in the etiology of cessation of function in the spinal cord in those cases in which the cord has not been literally cut through: Either there is a destruction of axis cylinders directly consequent to the impact, or else, owing to the impact, there is an edematous and hemorrhagic outpouring into the cord tissue, which by its pressure and chemical activity inhibits temporarily all conduction function, or destroys permanently the spinal cord.

In suggesting a possible treatment to aid and abet an autorestoration, it is obvious that the hypothetical factor of direct injury to the axis cylinder by the impact is beyond our reach, and that we should better confine our attention to the amelioration of the heightened intramedullary pressure.

This has been tried in years past by various means, such as cupping and other antiphlogistic devices. But the amount of benefit obtained has always been open to much doubt and in the fortunate cases, where restoration has taken place, the surgeon has found himself unconsciously imbued with a *post hoc non propter hoc* feeling.

THE SYMPTOM-CONTENT OF LONGITUDINAL SECTION OF THE SPINAL CORD

In order to ascertain the symptom-content of longitudinal section of the spinal cord, I performed laminectomy on a number of dogs. The dura mater was incised in the median line and held apart gently by means of traction sutures. Then with a very fine canaliculus knife longitudinal incisions from 2 to 3 cm. in length were made. In some cases a single incision in the median line, in others, bilateral incisions from the emerging posterior roots forward and inward were made. The incisions were carried completely through the cord. When the dogs came out of ether, they were able to stand and walk, showing very little weakness or awkwardness in walking. There was very little, if any, exaggeration of the reflexes of the hind limbs. A few days sufficed for the animal to recover his normal motor capabilities.

* From the Department of Experimental Surgery and the Department of Neurology in the University of Pennsylvania. Read at the thirty-seventh annual meeting of the American Neurological Association, Baltimore, May 11-13, 1911.

1. Allen, A. R.: Injuries of the Spinal Cord, THE JOURNAL A. M. A., March 21, 1908, p. 940.

2. Am. Jour. Med. Sc., May, 1908.

This finding is at variance with the teaching of some of the older physiologists, who have reported paraplegia of spastic type after this procedure.

I cannot but believe that when paralysis ensues after this operation, it is most likely due either to cutting the cord obliquely owing to faulty technic, or else is secondary to inflammatory change from imperfect aseptic precautions. From this work I conclude that median longitudinal section of the spinal cord of the dog is provocative of no symptom of note.

EXPERIMENT OF MEDIAN LONGITUDINAL INCISION IN CASES OF HYPERIMPACT

Given, as the hypothesis, that there is a twofold factor after the impact: (1) the direct injury to axis cylinders from the impact; (2) the outpouring of serum and blood into the substance of the cord; given the condition of the closely investing pia-arachnoid and the inability of drainage; given the comparative absence of symptoms after median longitudinal incision into the cord — the corollary which presented itself was: What effect would a median longitudinal incision into the spinal cord have on subjects submitted to hyperimpact?

The factors suggesting this course were the need for spinal cord drainage, thereby accomplishing a spinal cord decompression, and the fact that the heteromeric neurons in the dog and in man are not of vital importance.

In five dogs I have used a hyperimpact of 540 gram-centimeters (30 gm. at a height of 18 cm.), and then made a median longitudinal incision from 1 to 1.5 cm. in length directly through the impact level and passing altogether through the spinal cord. These dogs made uneventful recoveries, in the worst instances showing only a slight spasticity and awkwardness in the hind limbs after recovery, but not enough to prevent running and jumping.

This impact would have led to the dire consequences which I have pictured above, had not the median longitudinal incision been made. The dogs would have died had not the spinal cord been drained.

DETAILED DESCRIPTION OF OPERATIVE PROCEDURE

An incision of about 6 cm. is made over the spinous processes down to the fascia. The fascia is incised and the muscles pushed well to the side by means of a periosteal elevator. Three spinous processes are cut off by means of bone forceps, and then the lamina of one vertebra is sawn through on each side and the fragment of bone elevated and removed. Further enlargement is obtained by means of specially fashioned rongeur forceps. It is necessary to have at least 3 cm. of the cord exposed so that careful observation can be made. The epidural fat is now wiped away, the impact instrument adjusted and a strong reading-glass focused on the segment of the cord to be struck. The blow is struck, and there is a single jerk of the lower extremities.

The instrument is instantly removed, when it is noted that instead of the cord being the natural color and the dura mater showing as an almost transparent covering through which the small vessels are easily visible, we have now to deal with a dark bluish-purple, swollen mass. I now take a very fine curved needle, and clamping it in a pair of mosquito hemostats I use it as a tenaculum to lift the dura preparatory to incising it centrally. If this incision be carefully made, there at once bulges out of the opening of 2 cm. a dark, beefy-red mass. This is the greatly distended pia-arachnoid. This hyperdistention of the pia-arachnoid extends longitudinally about 4 cm., and when torn by means of a fine tooth forceps it subsides in a great gush of blood and cerebrospinal fluid. It will now be seen that the substance of the cord appears pinker than it should normally.

A median longitudinal incision of at least 1 cm. is made completely through the cord, following which there is a goodly outpouring of blood and serum from the cord substance.

After the active bleeding ceases, the muscles are brought together by a close row of buried Pagenstecher sutures. The fascia is closed by means of a continuous Pagenstecher suture and the skin wound by means of Michel clamps. The dura mater in the dog is too tight to warrant trying to suture it, as would most certainly be indicated in man.

The dog is completely paraplegic following the operation, and it may be three or four days before there is any indication of return of power. In a week's time he is standing and moving about his cage with a very spastic gait. Little by little the power returns and the spasticity diminishes. The end-result is a complete restoration of motor power. The animal is able to run and jump and has complete control of bladder and rectum.

The only point in the convalescence which may give trouble is the development of what I might term an artificial spina bifida. Owing to the difficulty of closing the dura mater in the dog, there is a leakage of cerebrospinal fluid upward forming a fluctuating tumescence, possibly the size of an egg, at the seat of operation. This it is my practice to evacuate by means of an aspirating needle under the most stringent aseptic precautions.

This experimental work has been carried out under full ether or cloroform anesthesia; and at no time have the dogs given evidence of suffering pain.

GENERAL CONSIDERATIONS; OUTLINE OF FUTURE WORK IN THIS FIELD

There are many steps between the results above mentioned and the adoption of the median longitudinal incision through the injured area as a desirable method of procedure in cases of spinal cord injury in fracture dislocation in the human subject.

The first important step to determine is: How long after the injury to the dog's spinal cord can one wait and still obtain the good effect of the drainage from median longitudinal incision?

I shall conduct a series of cases of hyperimpact in which the median longitudinal incision is made two, four, six and twelve hours after the impact; then a series in which a period of twenty-four hours elapses before the cord is cut.

I have already tried to aid the drainage by applying a Bier stasis-hyperemia cup over the laminectomy area the day after the impact operation of median longitudinal incision had been performed. This I applied for half an hour twice a day, but the result was most unde sirable. The dog showed every symptom of complete transverse lesion shortly after the first treatment and died about four days later. On histologic examination, I found the gray matter of the cord greatly softened and hemorrhagic for a distance of 2 cm. above and 2 cm. below the impact area. It looked just as if the gray matter, naturally lacking in *Widerstandsfähigkeit* (resisting power) had given way to the negative pressure.

Of course, this is only one case in which the Bier's method was used. It is altogether possible that, with a more gentle suction, a better or favorable result might have been obtained.

I wish to call attention to a point which has impressed me greatly in all this work. I refer to the effect of severe hemorrhage during the operation on the period of convalescence.

Hitzig[3] has shown the baneful effect of exsanguination on the central nervous system. I also have noted in a previous work the great change in conductivity in *the lateral columns of the spinal cord in animals (dogs)* slowly exsanguinated.[4] There is no doubt to my mind that whenever I had much hemorrhage, the animal's convalescence was prolonged, his spinal cord symptoms more severe than the impact would warrant and the chances of an infection greatly augmented. I am convinced that this is an important element in the failure of operations on the brain and cord.

It is not my purpose to take up the histopathology of this work until a future communication. I shall only say that I have been surprised at the amount of ascending and descending degeneration that I have found by the Marchi method in the spinal cords of dogs which had recovered their motor power completely and which I had killed in order to make the histopathologic study.

My tentative conclusion is that in cases of fracture dislocation of the spinal column in the human subject, in which there exists the symptom picture of transverse lesion of the spinal cord, it were well to perform the operation of laminectomy at the earliest possible moment, and if the cord be not completely severed to make a median longitudinal incision through the area of impact by means of a fine canaliculus knife in order to drain the injured tissue of the products of edema and hemorrhage.

2013 Spruce Street.

Protective Detention.—Dr. Quinton, an English criminologist, is quoted by G. A. Auden (*Jour. Crim. Law and Criminology*) as saying: "Female offenders who are of weak intellect will gain incalculable benefit from the scheme of the royal commission, which provides for their removal from prison altogether. This class—a very pitiable one—never has been, and never can be, rationally dealt with under a short sentence system. Their vicious habits and criminal propensities soon alienate them from relations and friends who in despair of controlling them, abandon them to their fate—picking up a living on the streets. Petty thieving, drunkenness and prostitution bring them back to prison time after time, their only gain from imprisonment being the protection it affords them for the time being from the perils of the street, which, in the case of feeble-minded girls and women, are appalling. They need not only preventive but protective detention in some kind of institution other than the prison, for a much longer period than any term of penal servitude their offense would justify."

SEVERAL UNUSUAL JOINT CASES

THEIR TREATMENT AND THE RESULTS *

GEORGE W. GUTHRIE, M.D.
WILKES-BARRE, PA.

In reporting the following rather unusual cases I claim no originality, but simply aim to show what thorough asepsis, accuracy of adjustment and secure fixation will accomplish.

I make no reference to a rather large number of other fractures occurring in a field in which traumatism contributes greatly to the work of a surgeon, including fractures of the patella, nor to cases of delayed union, and ununited fractures occurring in the shafts of bone in which the open method and direct fixation have been called into use.

CASE 1.—The first case may be summarized as follows: Complete separation of the right olecranon, extensive injury of the soft parts, nailing, straight splint; complete restoration of function.

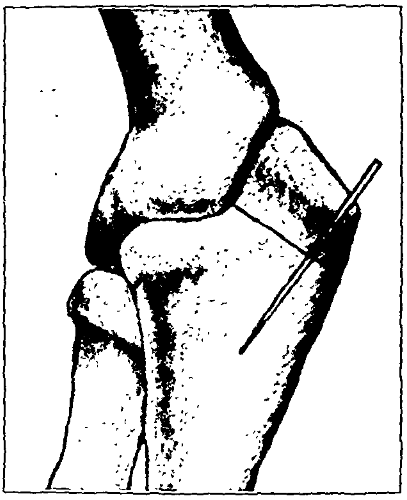

Fig. 1.—Method of fixing the broken fragment of the elbow joint in Case 1; the wire nail in position.

The patient was a male, aged 17, a pattern maker's apprentice. The injury was received by elbow joint coming in contact with a band saw; wound in soft parts 4 inches long across posterior aspect of elbow; olecranon severed ¾ inch below upper end; trochlear surfaces of joint scratched by saw; fragment of olecranon retracted by triceps. Reduction was effected by placing the arm in a straight position; fragment secured in place by driving a cast-steel wire brad, 1½ inches, No. 16, through fragment and into shaft of ulna (Fig. 1); wound closed with interrupted silk sutures, skein of catgut for drain, and straight anterior splint applied; wound healed without suppuration; nail was removed when it became loose, probably in the third week. Figure 1 shows the nail in position. The operation was done in the boy's home on a common kitchen table, a range for a sterilizer, a dish pan for instrument tray, in which instruments, nails, tack hammer, all were thoroughly sterilized. Passive motion was begun at the end of five weeks; six months after the injury the functions of the joint were perfect. Figures 2 and 3 show the limb in *straight position* and full flexion.

CASE 2.—The patient, a boy aged 10, was thrown from a horse while riding in the street; both condyles separated, probably an inch above the lower end of the humerus; distal end of proximal fragment thrust through soft parts in front of joint. Every precaution to produce an aseptic condition was taken. Complete reduction under anesthesia was effected by inserting fingers into the wound and securing perfect apposition of fragments, forearm was flexed on the arm and secured by a strip of adhesive plaster; the external wound was then dressed, and the upper extremity bound to the side of the body without a splint, as practiced by Mr. Robert Jones. Improvement was rapid and satisfactory; wound remained surgically clean; passive motion commenced at the end of the fourth week.

[4] Allen, A. R.: Hemorrhage Into the Ventricles, THE JOURNAL A. M. A., July 18, 1908, p. 216.

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Result: A complete restoration of function without deformity, as Figures 4 and 5 will show.

CASE 3.—This is the analogue of the first case. The patient, aged 42, a foreman carpenter, was at work on a scaffold at the second story of a building; a freshly ground hatchet lay on the floor of the scaffold. The scaffold fell, and when the patient was found, the hatchet had severed the head of the left tibia ¾ inch from the articular surface. The line of division extended three-quarters through the bone, then split upward into the joint. The incision in soft parts was 5 inches long. The severed fragment was secured in perfect position by two silver nails driven through the fragment into the shaft of the bone, the ends protruding from the upper flap of the wound about two inches; severed patellar tendon, ligaments, and other soft parts were closed with catgut, aseptic dressings applied and the whole limb encased in a plaster cast. The nails became loose in two weeks and were removed; cast removed at the end of four weeks, and passive motion commenced. Here the healing was without suppuration.

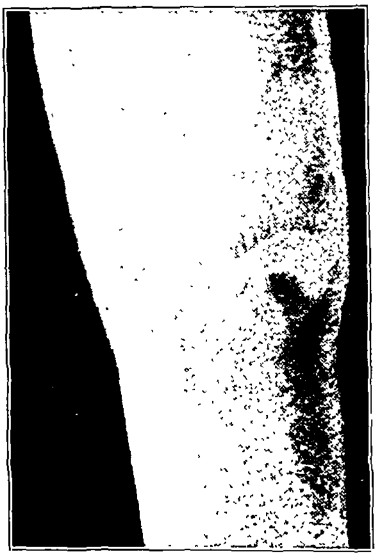

Fig. 2.—The result in Case 1, the arm held straight.

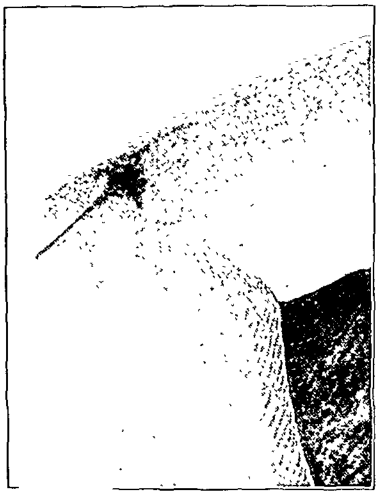

Fig. 3.—Showing the result with the elbow flexed in Case 1.

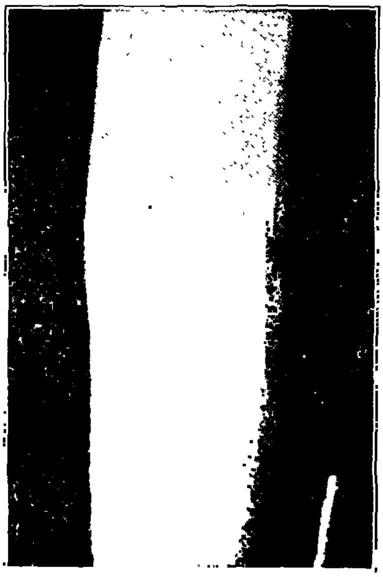

Fig. 4.—Showing result in Case 2, separation of the condyle of the humerus, the distal end of the proximal fragment having been thrust through the soft parts in front of the joint; complete restoration of function without deformity.

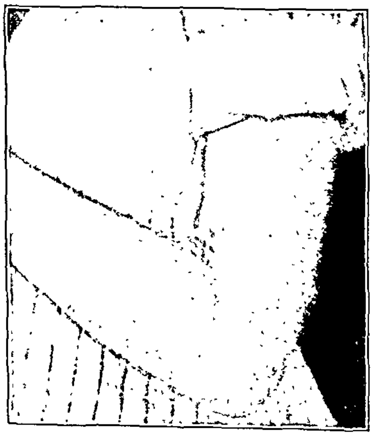

Fig. 5.—Showing result in Case 2 with the elbow flexed.

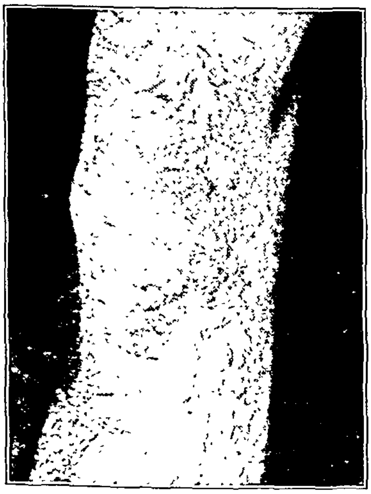

Fig. 6.—Accidental excision of upper end of tibia with healing and restoration of function, Case 3.

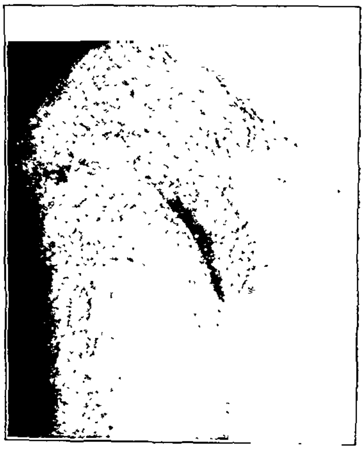

Fig. 7.—Showing result in Case 3 with knee flexed.

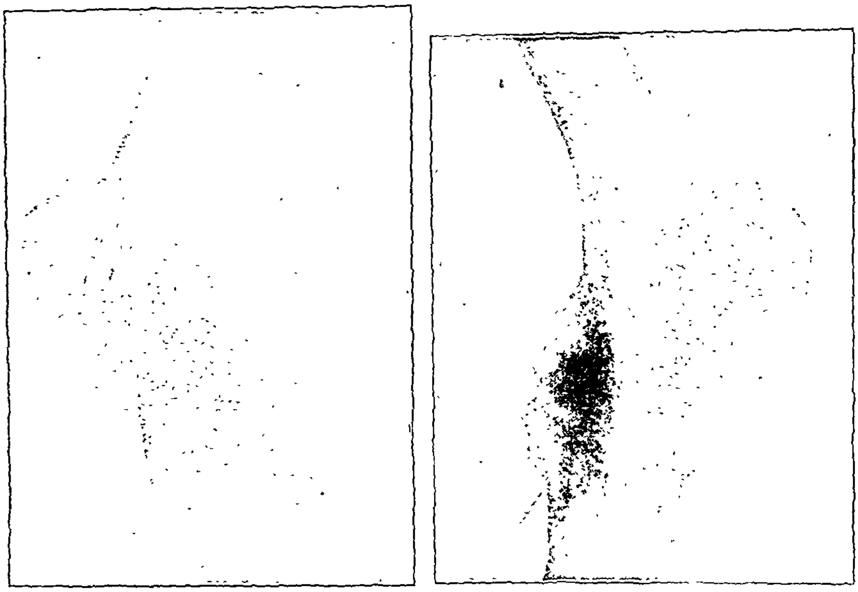
May 13, 1911, the patient came to my office; motion of left knee as good as in the right; conformation perfect, no difference to be observed. Illustrations (Figs. 6 and 7) taken May 13, 1911, confirm this.

CASE 4.—Patient, a woman, aged 48, 5 feet 2 in. in height, when she could stand erect, weighing about 160 pounds, came into my office in November, 1909, walking like a duck; legs flexed on thighs at an angle of 45 degrees, and ankylosed; for fifteen years she had had what was called rheumatism. The left elbow joint and the knuckles of right hand were, also, partially ankylosed, and the joints enlarged; also left bunion joint. An acute attack five years before was accompanied by chills, fever (temperature 105 F.), sweating, etc. The patient had always been regarded otherwise as a healthy woman. The menopause occurred at 39. The joints became fixed four years previously and had remained so. She had been treated in sanatoriums with baths, massage, electricity, etc. Her mother had had rheumatism in her knees.

The skiagraphs (Figs. 8 and 9) showed a considerable amount of exudate, and both patellas fastened by what appeared to be bony adhesions.

What to do for her was a puzzle. Forcible extension under ether would be attended with great danger to the soft parts, especially the blood vessels; tenotomy would be equally dangerous. Assisted by my son, Dr. Donald Guthrie, I operated Dec. 6, 1909: semi-circular incisions were made across the knees above the patella and through the tendons; on separating the left patella from the head of the femur, the articular surfaces were so injured that the patella was removed. The next step consisted in removing about an inch of the lower end of the femur with mallet (a potato masher) and a broad-bladed chisel. It was found then that the leg was quite easily straightened. A similar procedure was followed in the right side, except that the patella was not removed; both wounds were closed with catgut, without drainage, and plaster casts applied, and allowed to remain six weeks. Healing was satisfactory and good firm legs were secured.



Figs 8 and 9.—Skiagraph showing complete ankylosis of knee-joints in Case 4

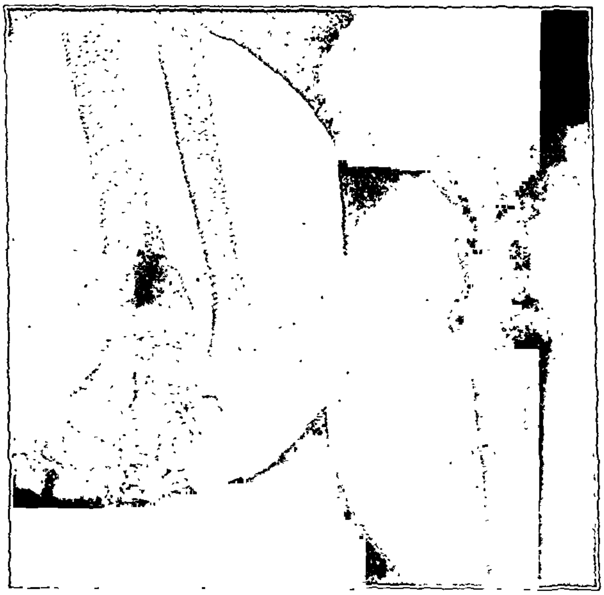


Fig. 12.—Skiagraphs showing the very satisfactory apposition secured in the compound, comminuted fracture at the wrist-joint in Case 5.

Present condition: The left knee is flexed about 10 degrees and fixed; the right is straight and has a motion of about 10 degrees. The cosmetic results are not the best, but the function of walking has been restored; the patient no longer walks like a duck, but stands upright like a human and goes everywhere, up and down stairs, all over the house, walks the streets, visits her friends, goes to weddings, and is a very happy woman (Figs. 10 and 11).

Fig. 10.—Anterior view of knee-joints following operation in Case 4.

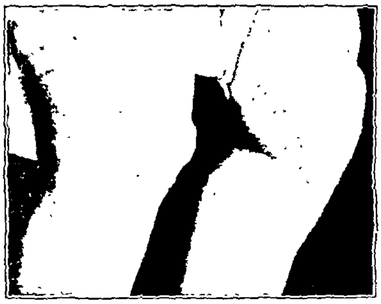

Fig. 11.—Lateral view of knee-joints in Case 4; left knee-joint fixed at an angle of ten degrees; right knee has motion of ten degrees.

I know the conduct of this case admits of argument: It may reasonably be asked whether we did the best thing for the patient under all the circumstances. Would it have been better to have attempted joint action by interposing a flap of fascia between the ends of the bone? Our reasoning was this: The first demand is a firm, strong knee-joint; the second, a straight leg; and the third, motion if possible.

Here was a patient, with a bad history for five years, weighing 160 pounds. A weak, flail-like joint would render her latter condition far worse than her former. We were painfully aware of the risk we assumed, but our asepsis was good, healing was kind, and good, firm knees resulted. A 10 degree flexion in the left does not interfere with her

Fig. 13

Fig. 14

Figs. 13 and 14.—Two photographs showing the cosmetic result secured in Case 5.

walking, and the same degree of motion in the right makes them correspond. I invite discussion and criticism.

Case 5.—This patient, aged 40, a painter of tall chimneys, stacks, etc., was brought into the hospital Sept. 2, 1910. He had fallen from a ladder 25 feet to a roof, thence to the ground, 15 feet. The right wrist presented an alarming condition of traumatism: a Colles fracture of the radius; the ulna was driven through the soft parts on the front aspect of the wrist, protruding 1½ inches; the styloid process was broken off, and the articulating surface comminuted. It was one of the worst-looking injuries I have ever seen.

Ether was administered; the fractured end of the ulna was trimmed up; then the dislocation was reduced, and with fingers in the wound, the fragments of the radius were accurately replaced. I held them in this position while my intern, with a good pocket knife, fashioned the splints according to my direction. The palmar splint was narrowed at the location of the external wound so as to admit of a change of dressing; the posterior splint made no pressure over the end of the ulna.

Healing was satisfactory, and June 3, 1911, the patient presented himself with the following result: The end of the ulna was much thickened from a superabundance of callus, pushing the hand to the right side; pronation, supination, flexion, and extension are all present, and he has a good degree of flexion of the fingers—not perfect, but improving.

The accompanying skiagraph (Fig. 12) was taken, and shows the very satisfactory apposition secured, and the accompanying photographs (Figs. 13 and 14) show good cosmetic results.

109 South Franklin Street.

A SIMPLIFIED PERITONEUM-GRASPING FORCEPS

JOSEPH RILUS EASTMAN, M.D.
INDIANAPOLIS

The abdominal viscera forceps here illustrated is not essentially different, so far as its efficiency or field of application is concerned, from other viscera forceps now in use. Its advantages rest in the ease with which the rubber tubing at the circular jaws may be replaced when worn or damaged in sterilizing, the security of the grasp, and in its durability.

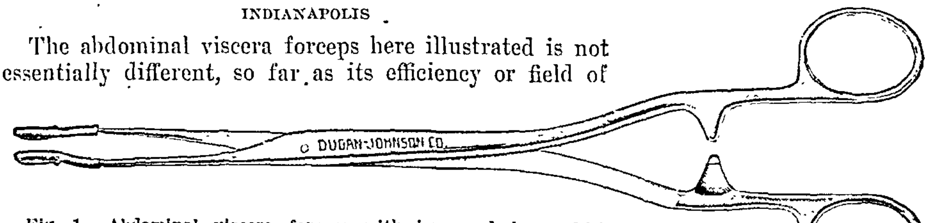

Fig. 1.—Abdominal viscera forceps with improved jaw, which increases the security of the grasp without injury to the part, and admits of easy replacement of the rubber covering.

The short elbow curve of each shank above the circular jaw allows complete coaptation of the rubber-covered rings, so that pressure is not brought to bear at a point, but over a larger area of the intestine, or other peritoneum-covered viscus.

The steel of the instrument is so tempered that crushing of delicate tissue is practically impossible. The grasp, however, is firm enough to be reliable.

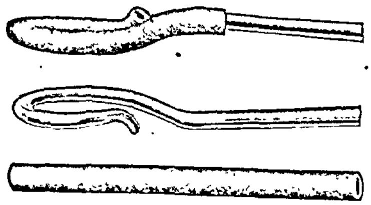

Fig. 2.—Showing the folding back of the end of the forceps blade and the short elbow curve of the jaw, which allows of pressure over a larger area of intestine. The rubber tube covering is also shown.

Sterilization by heat soon ruins the rubber of gut forceps, or renders it sticky. Therefore, it is desirable that the rubber be easily changeable. In the forceps shown in the drawings, small red gum tubing may be passed over the open rings and slipped off as often as required. The "heels" of the open ring are turned back in order that the ends of the tubing may be deflected from the grasping surfaces. For the same reason the tubing should be slipped along the forceps far enough to bring the proximal ends of the rubber covers over the elbow curve, and a short distance along the shank.

331 North Delaware Street.

BONE-GRAFTING TO FILL A GAP BETWEEN TWO PORTIONS OF A TIBIA*

F. A. McGREW, M.D.
LAPORTE, IND.

History.—At 11 p. m. of a day (Aug. 10, 1909) during which a little girl, 6 years old, had been wading in the water, she was taken with a violent headache and high fever. She seemed somewhat better the next day, but vomited in the afternoon. Forty-eight hours after the first symptoms appeared she grew worse again, had severe headache and high fever, with pain in the left side of the chest. A physician was then called. After a few days the pain disappeared from the left side and "moved across" to the right.

About a week later she had terrific pain in the right leg, or, as it seemed to the attending physician, in the knee-joint. She suffered "frightful pain" for a week, meanwhile undergoing treatment on a mistaken diagnosis of rheumatism. The knee and leg below the knee swelled, and a bulging abscess having appeared over the front of the leg below the knee, she was brought to the hospital and incision made for drainage. A few days later I was asked to see the patient in consultation.

The leg was much swollen on account of cellulitis. There was a small pre-tibial knife opening just below the patellar tubercle, through which pus was discharging. The leg was drawn up in extreme flexion, and when any attempt at movement of it was made there was every evidence of excruciating pain. The general condition was one of septicemia.

I advised free drainage of the tibial shaft, and the application of a posterior splint after straightening the leg under anesthesia, dressing slightly flexed. Only the latter part of the advice was followed. The child gradually improved, and finally was sent home. I had also advised that all the dead bone be removed eight weeks from the beginning of the tibial involvement. This advice, however, was not followed, and it was not until fifteen weeks after the initial symptoms in the leg, that the case came to me through the courtesy of Drs. Sutherland and Fargher, of La Porte. The patient was then in the Holy Family Hospital. There was profound septicemia, high temperature, constant very rapid pulse, emaciation, several discharging openings and great cellulitis of the leg extending to the thigh, and, in general, a very bad condition.

Operation.—Operation (November 29) was at once undertaken with the object of draining the pus cavities throughout the cellular tissue and shaft, with the intention of completing operation at a future date after suppuration had been controlled and the general condition improved. But, having once begun the operation, there did not seem to be any favorable place to stop as intended. An incision was made along the front of the tibia. The whole of the upper three-quarters of the shaft was found involved in the necrosis and removed. The upper extremity of the shaft was involved, the necrosis extending to the articular surface of the knee-joint, leaving on either side what appeared to be a sound shell or shelf of compact bone corresponding to the tibial tuberosities. New islands of bone, from 1/8 to 1/4 inch thick, had formed here and there on the periosteum. These were removed. The cellulitis was drained with rubber tubing, passed through in various directions. Pus bathed the whole leg. The cavity left after the removal of the necrotic shaft, lined by its periosteum, was cleansed and closed with catgut and the skin closed with silkworm gut to the upper end where an opening was left through which the cavity in the upper extremity of the bone was packed with iodoform gauze.

---

* Read before the Laporte (Ind.) County Medical Society, June 9, 1911

Subsequent History.—As expected, suppuration of the periosteal cavity promptly supervened, but on account of the excellent drainage her temperature ranged lower, and her pain and general condition improved continuously. At first, dressing could only be done under general anesthesia, but with the improvement this was soon avoided.

There was little change, except a gradual improvement in all the conditions until May 7, 1910, when the cast was removed on account of an eczema of the leg and foot. A week later it was reapplied but thereafter it was a constant fight to keep the eczema within limits which would permit the retention of the cast.

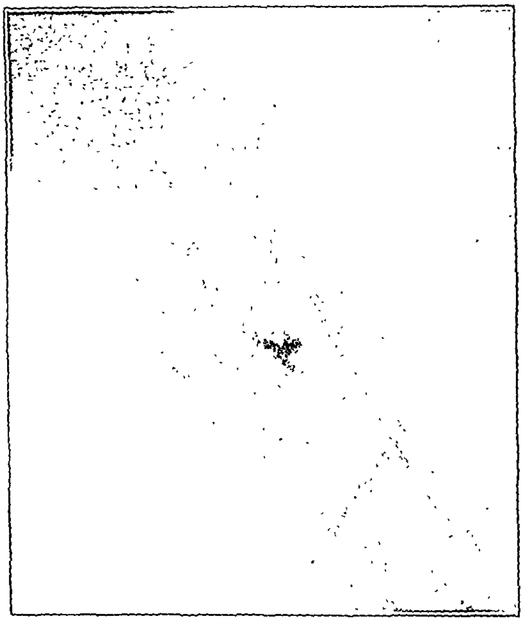

Fig. 1.—Skiagraph made Oct. 2, 1910. It shows the new shaft after ten months' development, associated with constant suppuration. Also the gap between the new and old portions of the bone.

Bismuth paste was at this date in May being injected into the sinuses leading into the upper extremity of the bone and also near the center and at the lower end of the operation wound. These had gradually improved, the upper one having closed entirely. The eczema was much better. The bone in the tibia had reformed enough to be solid, except at the upper end, where there was free mobility.

The cast applied in May was worn until July 2, when, the sinuses having all closed, a solid cast was applied and allowed to remain without change for three months. When removed, there was found to be mobility at the lower end of the newly formed shaft, while that at the upper end had disappeared and the bone was solid at its upper extremity.

A skiagram (Fig. 1) was taken Oct. 2, 1910, when the cast was removed. It showed the new shaft to be well developed toward the upper end, but dwindling toward the lower end, where it ran down irregularly to a blunt point, separated one-half inch from the rounded upper end of the lower residual portion of the tibia. Her general condition was excellent. She had been growing rapidly, and going to school during the fall months.

Second Operation.—The cast was left off a month hoping that movement might stimulate some further development of bone, but without result. Nov. 4, 1910, another operation for the purpose of closing the interval between the new and old portions of the shaft was undertaken. The incision extended from the summit of the inner malleolus diagonally upward and outward to the anterolateral aspect of the leg. The whole anterior and external surfaces of the lower tibial remnant were exposed, and also the lower end of the new-formed shaft. The two extremities were found to be separated by fibrous tissue in which was imbedded a small, irregularly shaped piece of bone. Union would not have occurred. The fibrous tissue was removed and the ends of both bones freshened by excision of their extremities, after which it was found that a gap of about one inch required filling.

With mallet and chisel a flap including periosteum and the full thickness of the bone was cut from the anterior surface of the distal portion of the tibia, leaving an attachment of periosteum at its upper end. This flap was turned about and its periosteum stitched to the periosteum along the outer border of the proximal portion, bridging the gap. The endosteum and periosteum had been carefully handled and preserved. The wound left in the bone by the removal of the flap was packed with iodoform gauze, and also the interval between the two bones which had not been filled by the flap. A dressing over all and a cast were applied, the latter being provided with a window for dressing the wound.

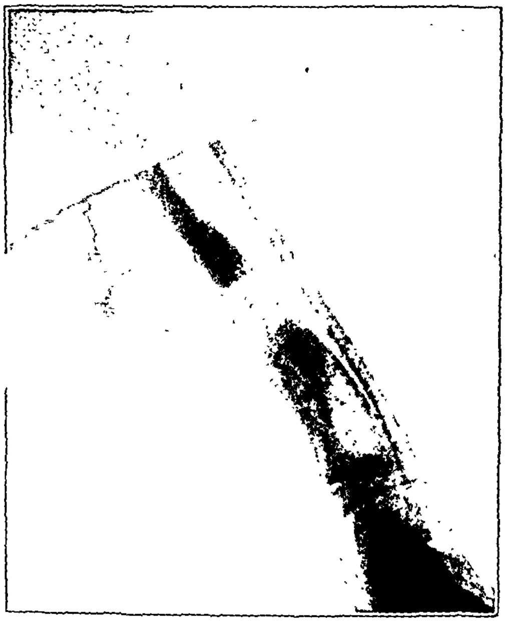

Fig. 2.—Skiagraph made June 1, 1911, seven months after the flap operation. It shows not only that the gap has been filled with new bone, but that the entire new shaft has been spurred to vigorous growth.

There was some swelling following the operation, the wound stretched apart throughout its entire length, and bone was exposed over a small area. When the wound first became red and swollen it was dressed with moist boric dressing and later with dry dressings and Peruvian balsam. It appeared to heal rather rapidly. The cavity corresponding to the interval between the two bones unfilled by the flap was kept carefully packed in order to keep the tissues from crowding in between the two ends of the bone. Gradually this interval filled with granulation tissue, but left a small discharging sinus. Bismuth paste was systematically and continuously injected into this sinus during the next several months. March 11, 1911, a small sinus was noted. A probe passed in came on dead bone which seemed to be movable, so a small sharp pointed artery forceps was inserted and the irregular jagged fragment of bone was withdrawn. There was good use of the ankle-joint. The knee-joint was also unrestricted in movement. The bone on this date seemed firmly knit together and as large over the former gap as the shaft above and below. There was no abnormal mobility. Somewhat more than three months therefore elapsed after bone-grafting before the union was complete, and at that time the gap had been completely filled.

The second skiagram (Fig. 2) was made about June 1. It shows the gap filled with bone. Also, it is interesting to observe that the new-formed shaft which was spindling and weak before the last operation had now become particularly strong toward its lower end, apparently stimulated to overgrowth by the coupling of the two portions by means of the bone-graft.

There is shortening to the extent of three-fourths of an inch. I am unable to say at present whether this is in part on account of injury to the epiphyseal line of growth or entirely because of the action of the muscles not wholly counteracted by the splint-like effect of the fibula. That considerable pressure was put on the fibula is shown by the fact that the upper extremity was forced loose from its joint on the external tuberosity and now occupies a higher position than normal, where it is still movable. There is a backward curvature to the reconstructed tibia, due, I think, to the same inability to control muscle action. There is still a small sinus leading down to necrosed bone, which I believe will be absorbed in time, without the necessity of further operation. Bismuth paste is being injected regularly and there is no suppuration.

The turning up of a bone-flap from the distal portion to fill the gap in the tibia was only the application of the well-known principles of the grafting of the soft tissues. I have no knowledge of a similar case.

I wish to acknowledge the excellent skiagraphs made for me by Dr. A. C. Simon.

NOTE.—At the time of correcting the proof (August 1) the patient is using the leg with no restrictions, and the remaining sinus has closed. The head of the fibula no longer shows abnormal mobility.

TRANSPLANTATION OF A PORTION OF THE TIBIA INTO THE SPINE FOR POTT'S DISEASE

A PRELIMINARY REPORT

FRED H. ALBEE, M.D.
Assistant Professor (Head of Department) of Orthopedic Surgery, Cornell University; Professor and Adjunct Professor of Orthopedic Surgery, University of Vermont, and Post-Graduate Medical School and Hospital, etc.
NEW YORK

The following is a final development, from a series of studies, on the application of osteoplasty in the treatment of Pott's disease of the spine.

I was induced to undertake this experimental work on the spine, on account of the excellent operative results obtained in tuberculosis of joints elsewhere in the body where bony union with its perfect support and immobilization has caused the tuberculous process to disappear so rapidly, although only a fractional part of the tuberculous tissues was removed. This has been especially exemplified in my ankylosing operation on the hip, when applied to tuberculous ostitis of that joint, and also in erasion of the knee under similar circumstances. The fact that it is only necessary to secure bony stiffening in tuberculous joints, by operation or otherwise, in order to get a rapid disappearance of the tuberculous process has been emphasized very strongly in the recent writings of Ely, both in his clinical and his pathologic studies. Previous to the herein reported cases, five patients were operated on and three or four spinous processes were split with a chisel or bone forceps for from 1 to 1⅓ inches from their tips, into equal halves, either through a plane approximately parallel with the long axis of the trunk or at right angle to it. The tip of the lower half of the superior vertebra was then brought into approximation with the tip of the superior half of the next lower vertebra after green-stick fractures of each and fastened with heavy kangaroo tendon. Chips of bone from the spinous processes were then placed in between so as to insure further bone union between these vertebræ. Mechanically this event (the union of spinous processes of neighboring vertebræ) acts in two ways: First, if we consider each vertebra a lever (as it properly is) with the fulcrum at the lateral processes, its short arm, the body of the vertebra and the long arm of the lever, the spinous process, then by causing a bony union of the posterior part of the lever, we shall prevent by leverage a crushing together or approximation of the bodies or the anterior arm of the lever.

Nature has done this, i. e., a fusing together of the posterior portions of the vertebræ involved, but unfortunately rarely, as pointed out by Brackett. This prevents absolutely any crushing of the bodies of the vertebræ and thus any further progress of the kyphosis or deformity. Secondly, and possibly not least, this formation of a bony bridge, connecting firmly the diseased vertebræ with the healthy ones on either side, acts directly as an internal splint on the vertebræ involved and furnishes more perfect support than any mechanical apparatus could possibly accomplish.

These assumptions are based, of course, on bony union of vertebra to vertebra as well as union of the green stick fractures of the vertebral halves.

This union has been satisfactory so far as can be ascertained, but on account of its uncertainty and the large amount of cartilage in the vertebræ of small children, with its slowness of union and early lack of support, it has seemed best to devise a procedure which would be possibly more reliable and also give support from the beginning. These requirements can be fulfilled in no other way except by a strong bone-graft.

The different sources from which to secure a strong bone-graft for an internal splint, which would give immediate support to the spine, were considered and the crest of the tibia was selected as by far the most desirable and accessible.

CASE 1.—*History.*—With this in view, R. C., a child aged 4, referred to me by Dr. E. H. Johnston, of Waterbury, Conn., was admitted to the Post-Graduate Hospital.

The past history was negative up to the time the trouble with the spine began. Several months before, the child had begun to have night "cries and sweats," and coincidently began to support herself with her hands on her knees. The mother thought that there had been a loss of weight and that the child was getting pale. There had been pain in the region of the stomach for the past two months. About three weeks before examination, the lump on the child's back was first noticed.

Examination.—This was negative except for a considerable kyphosis at the first and second lumbar vertebræ. The child stooped to pick up things from the floor with difficulty. The spine was rigid to passive and active motion in the region of the kyphosis.

Operation.—The patient was operated on June 9, 1911. Under ether, with the patient in the ventral position, an incision was made, directly over the tips of four spinous processes, with the kyphosis in the center. Each process was then split longitudinally for about one inch and a quarter into two portions with one-third of the process on the left and two-thirds on the right. The soft tissues between the processes were then merely separated by blunt dissection or by a *scalpel, parallel* with the muscles. Green-stick fractures were then produced at the base of the one-third portions of each of the processes. A wedge-shaped cavity was thus produced, ready to receive the bone graft. A compress of hot saline was then placed over the wound. The left leg which had been prepared for operation was then flexed on the thigh, so that an incision over the crest of the tibia anteriorly could be made. A prism-shaped piece of the tibia from its anterior-internal aspect was then removed by means of a chisel, with the periosteum intact on two of its surfaces. The graft taken was about 4 inches by 1 inch, by ½ inch. It was quickly removed and immediately placed in the interval between the portions of the spinous processes. The dense fascia over the tips of the processes was then approximated by interrupted sutures of No. 3 chromic catgut, thus holding the bone-graft very firmly in place. The skin was closed by a continuous suture of No. 1 plain catgut. The leg wound was treated in a similar way. The time of operation was fifteen minutes. There was no shock.

Result.—The child made a fine recovery from the anesthetic. The wounds healed by primary union. The child was discharged from the hospital July 17, 1911. The convalescence has been extremely satisfactory thus far. Muscular spasm of the spinal muscle has diminished very materially. However, it is obvious that it is too early to draw any definite conclusion concerning the final results of any of the cases herein reported, and this is a record of progress only.

Case 2.—*History.*—The patient, J. M. C., male, was a carpenter, aged 28. His family history was negative to tuberculosis. His present trouble began eight months ago with pain in his back which started in the lumbar region and shot into the thighs. He had night sweats all last winter, but no cough. There was a little pain in his right side when the patient walked and later there was pain in the left side also. There was a mass in the right groin for six months previous to the examination.

Examination.—This was negative except for moderate kyphosis involving the eleventh and twelfth dorsal vertebræ and the right psoas abscess, the size of a fist, just below Poupart's ligament. The spine was very rigid to all motion, both passive and active, in the lower dorsal and lumbar regions. The patient bent the spine with pain and difficulty.

Operation.—June 27, 1911, the Post-Graduate Hospital. Precisely the same operation was done as described in the previous case. The bone-graft from the tibia was much larger, however. It measured about 6 inches by 1⅛ inch by ½ inch. Both wounds healed by primary union. This case was discharged from the hospital July 15, 1911. The patient has gone back to work, wearing a Taylor spinal brace.

Case 3.—*History.*—The patient, W. D., was a boy aged 4½ years. His past history was negative except for measles and typhoid fever one and two years ago. He began to rest his chin in his hand eight months before examination. There was pain in the neck, which grew progressively worse, and which was complained of at about the same time. A lump on his back was noticed about six months ago.

Examination.—This was negative except for the spinal condition. There was a large angular kyphosis including the last cervical and first two dorsal vertebræ. There was a marked muscular spasm from passive motion. The patient bent with difficulty to pick things from the floor.

Operation.—July 14, 1911. Post-Graduate Hospital. This operation differed from the preceding ones only in reference to the bone-graft. On account of the angularity of the kyphosis, the bone-graft had to be molded into the segment of a circle in order that the corners would not project beyond the tips of the spinous processes distal from the kyphosis. The graft was about 4 inches by 1 inch by ⅜ inch, and included four spinous processes. Both wounds healed by primary union.

This patient is still on a modified Bradford frame. The convalescence has been very satisfactory thus far.

We have at present two cases on reversely bent Bradford frames for the purpose of securing a recession of the kyphosis before operating, and feel confident of holding the correction by the bone-graft.

SUMMARY

1. The inefficiency of present methods in the treatment of dorsal Pott's disease was tersely expressed by Schapps in 1905 as follows: "It is universally admitted that the forms [of portative apparatus] in general use and described in the standard text-books on orthopedics do not, even in the most skilled hands, control the deformity."

2. A firm bony splint with bony union to the vertebra involved and the healthy vertebræ on each side is supplied by this method, which assures not only the prevention of further deformity in two mechanical ways as stated above (leverage and splint action) but should also cause the immediate disappearance of the tuberculous process.

3. This method is believed to be preferable to any, where breaking or cutting of the spinous processes destroys entirely, or for the time being, until union takes place, the desired leverage of the spinous processes and their muscles and ligaments. Union is also uncertain where motion from breathing is present.

4. If bony union should not occur the same mechanical effects would still be largely obtained from the union of the internal bone splint to the ligamentous structures.

5. Perfect immobilization of the few involved vertebræ in the respiratory area of the spine is secured, which is a mechanical impossibility by means of any external apparatus, on account of the constant movement of the ribs, and the vertebræ attached.

6. Fortunately, on account of the anatomy of the part it is not necessary to enter the focus of disease; therefore primary union of soft tissues with immediate bone union can be expected.

7. The normal leverage action of the spinal muscles and the supporting ligaments on spinous processes is not interfered with.

8. The operation is by no means a formidable one. The technic is very simple.

9. When possible it is well to secure a recession of a kyphosis by long recumbency on a reversely bent Bradford frame. This method offers great promise of holding the correction obtained.

10. A bone-graft is far superior to an internal metal splint, because, by following Wolff's law it will become thicker and stronger if necessary to hold the weight or strain brought to bear on it, whereas in the case of an internal metal splint, suture or screw applied to the bone, no dependence can be placed on them to hold weight or strain, because of the bone atrophy and absorption which takes place directly around the metal. This occurs even when no strain is present.

I have found silver wire and screws which were placed through bone only a few months before, in the soft tissues where they had fallen through or out of the bone without being influenced by strain. For this reason and the always present danger of sepsis about buried metal, it would seem that bone-grafting will prove preferable to the internal metal spinal splint of Lange.

125 West Fifty-Eighth Street.

The Structure of Protoplasm.—We are generally agreed at present that it is inaccurate to speak of any one structure as common to all protoplasm, but many cytologists, among whom Bütschli, working chiefly on protozoa, was the first, believe that the different types are referable to one common generalized type which Bütschli described as alveolar in structure. A simple example of such modification of the alveolar into denser plasm can be easily demonstrated in the protruding pseudopodium of *Amœba proteus*.—Calkins in *Science*.

RESPIRATION VALVES

C. C. GUTHRIE, M.D.
PITTSBURGH, PA.

Some years ago I published a description[1] of an arrangement of valves for use especially in administering volatile anesthetics to animals in laboratory experimentation. The apparatus was designed primarily to avoid unnecessary waste of volatile anesthetics. An experiment with the first model constructed, in which an 8-kilo dog was employed, showed a saving of almost exactly one-half in ether when the valves were used, as compared to the amount used with the animal directly connected with the anesthetic bottle in the ordinary manner. This saving is due to the action of the valves in preventing air being forced through the bottle during expiration, thus displacing and carrying away ether vapor. And since expired air is warmer than inspired air under usual laboratory conditions, the increased vaporization due to raising the temperature of the liquid anesthetic is avoided. Furthermore, contamination of the anesthetic by condensation of water vapor is avoided. The valves require no adjustment or attention, as there is nothing that can get out of order. They have been used by the regular medical students in physiology and pharmacology at my laboratory for five years, and in no instance have they required any attention. One size suffices for half-grown cats as well as for large dogs, without any adjustment.

The apparatus commends itself for other reasons. For example, the audible but not noisy clicking of the valves furnishes a very reliable aural index as to the condition of the animal, and permits the closer concentration otherwise of the senses usually employed in constant observation of the condition of the animal. Or, if it is desired to collect the expired air for any purpose, this may be readily accomplished by connecting a suitable reservoir as a spirometer to the expiration tube. Owing to the desirable features enumerated, the valves are employed in all my operative work, connection with the dog or cat being made by means of an air-proofed hood or laryngeal tube (Figure 3).

The improved valves are shown in Figure 1; also, an additional valve of plunger type, which automatically regulates the entrance and escape of air from the lungs

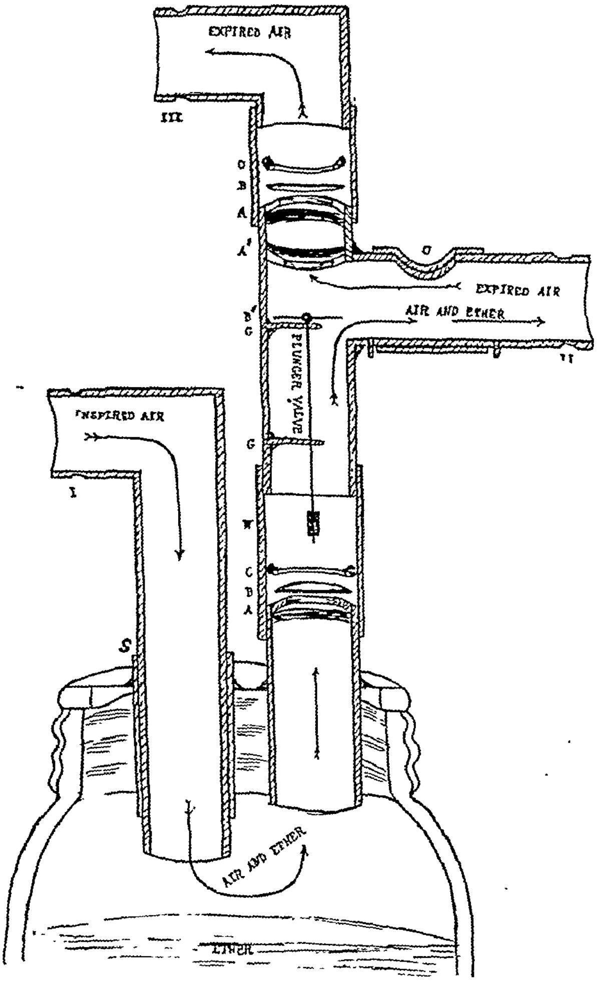

Fig. 1.—Respiration valves. I, entrance for air into anesthetic bottle. S, collar in which tube slides fo[illegible] at of ether. II, connection for laryngeal or [illegible] ming in tube and movable collar for adjust[illegible] air. III, outlet for expired air. By conne[illegible] the amount of expired air can be measure[illegible] with spirometer the expired air can be measured and collected for analysis. A marker may be connected with the spirometer and arranged to record on a moving surface the amount of expired air. A, valve seat; B, valve disk; C, valve stop; B', valve to close the opening at A' when artificial respiration is given by means of rhythmic or positive pressure through I; W, weight for regulating the action of valve in forced artificial respiration.

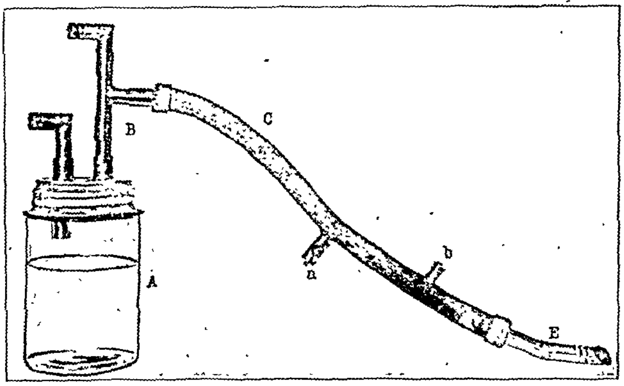

Fig. 2.—Anesthetic bottle, provided with respiration valves and connections.

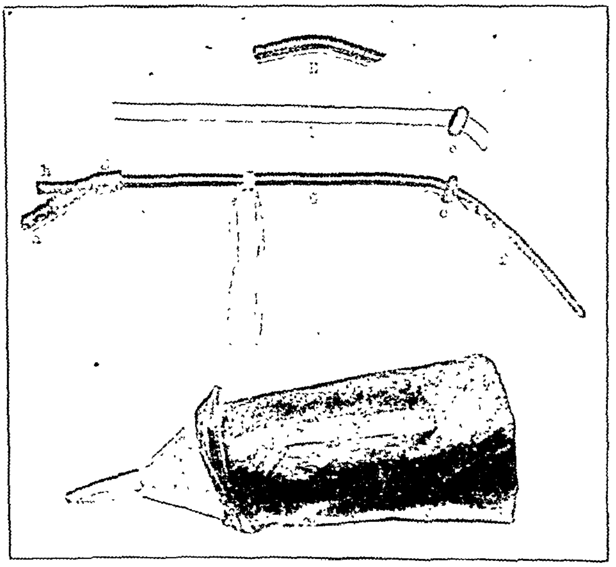

Fig. 3.—Attachments for administering anesthetics, for use with arrangements shown in Figure 2.

---

1. Guthrie, C. C.: Respiration Valves, The Journal A. M. A., April 6, 1907, p. 1183.

in intermittent pulmonary insufflation, is shown. In thus using the apparatus, a small vent is opened at *O*, to insure prompt opening of the plunger valve. The valves may also be employed in administering anesthetics in continuous pulmonary insufflation.

Figure 2 shows ether bottle, *A*, and valves, *B*, with rubber tube, *C*, for connecting with hood, *D* (Fig. 3); tracheal tube, *E*; laryngeal tube, *F* (Fig. 3); and laryngeal tube, *G* (Fig. 3), for continuous pulmonary insufflation. The nipple, *a*, on the tube, *C*, is for regulating artificial respiration, when the tube is disconnected from the bottle and air is forced into the lungs by connecting the supply directly with the free end of the tube. The nipple, *b*, is used for connecting a tambour to record intratracheal pressure changes. Both nipples, *a* and *b*, are provided with movable caps by rotation of which the openings, *c* and *d*, are controlled. Construction details of the nipples are shown in Figure 4. The method of attaching the air-tight sleeve to the metal funnel, which forms part of the hood, may be seen by reference to Figure 3. The free margin of the hood is held in contact with the skin by means of thin rubber tissue cut in the form of a strip, an inch or two wide and of sufficient length to encircle the base of the head two or more times. It is applied snugly, but not too tightly, over the margin of the hood, and is conveniently fastened by means of a serrefine clamp. The tracheal tube, *E*, which is of ordinary form, is made of polished or plated metal or glass and is introduced and tied in place in the ordinary way. The laryngeal tube, *F*, is of polished or plated metal or of glass. The curved end is somewhat sloped and flattened and is provided with a thick, soft rubber collar, *e*. A heavy ligature about a foot long is tied around the tube with a single knot a little to the outer side of the middle, in such a manner that the free ends of the ligature are of about equal lengths. Narrow cloth tape serves well for this purpose. To insert the tube, the animal is rapidly anesthetized until the muscles relax, which requires from about thirty to ninety seconds. It is then placed on a table with the head toward the light and the end of a short stick of soft wood is inserted in the corner of the mouth between the molar teeth on one side, the jaws being widely opened for the purpose. The tongue is then grasped with a towel held in the left hand and pulled forward. This brings the epiglottis into view, and with the right hand the curved end of the tube is passed over the epiglottis and into the larynx, until the rubber collar presses against the tissues. The ligature around the tube is then tied firmly about the lower jaw to hold the tube in place. After securing the ligature about the lower jaw and removing the stick from the mouth, the ends may be brought about both jaws and tied on the upper surface of the nose in front of the eyes.

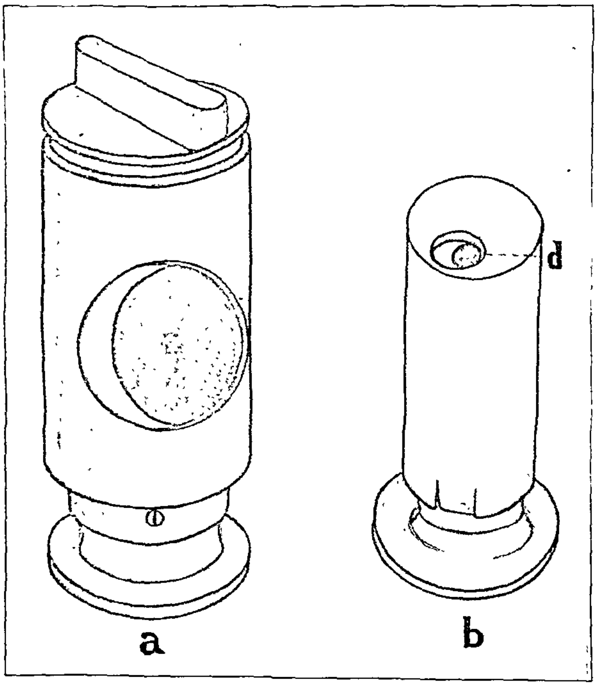

Fig. 4.—Enlarged drawing showing construction details of nipples inserted in tube shown in Figure 2.

The outer tube of the laryngeal tube, *G*, for continuous pulmonary insufflation, is of the same construction as the tube just described, and is inserted in the same manner. The inner tube, *f*, is flexible and of sufficient length to reach from the lips to the bifurcation of the trachea. It loosely fits the outer tube which it enters through a hole in the rubber sleeve, *g*, which it fits snugly. The outer end, *h*, may be provided with a glass or metal tube connector, for convenience in attaching to the compressed air supply. The free end of the rubber sleeve, *g*, is provided with a screw clip or other device such as nipple, *a*, Figure 4, for regulating the amount of outgoing air. The rubber sleeve which is disconnected from the end of the outer tube is removed along with the inner tube, before the outer tube is inserted. After the latter is tied in place, the inner tube is pushed through the lumen of the outer tube and secured in place by connecting the rubber sleeve with the end of the outer tube. The position of the end of the inner tube in the trachea is regulated by sliding it in the hole in the sleeve which it penetrates.

EXCISION OF PARIETAL PORTION OF TUNICA VAGINALIS FOR RELIEF OF PAINFUL TESTICLE FOLLOWING GONORRHEAL INFLAMMATION

GEORGE T. TYLER, M.D.
BUFFALO, N. Y.

Patient.—A soldier, aged 25, stationed at Fort Porter, N. Y., previous history unimportant, had gonorrhea with swelling of left testicle six months previously. The swelling subsided and at time seen, the patient had only a slight mucoid discharge, noticeable in the morning, but complained of painful left testicle.

Examination.—Urine had shreds in the third glass. No stricture. Prostate on palpation was normal; right testicle normal; left testicle not swollen, but very painful and tender on palpation. Any effort to determine outlines of epididymis and first portion of vas caused so much pain that it could not be done.

Treatment and Course of Disease.—It was thought that the lumen of the globus minor was constricted, and the testicle was explored with the idea of excising this portion, and anastomosing the vas with the globus major. But when exposed the epididymis and vas were found normal. Attention was then directed to the testis. Here it was found that the cavity of tunica vaginalis was entirely obliterated; the parietal was entirely adherent to visceral layer by firm dense adhesions and was much thickened. This was dissected off and excised entirely. The testicle was returned to the scrotum and the wound closed with a small drain. Following operation, the tes ticle was swollen for a short time. This soon went down and in ten days healing was complete. Patient was up at this time; symptoms had entirely disappeared. He returned to work two weeks after operation, doing general work around the stable. Hexamethylenamin (urotropin) was given for the urethral condition. The patient was seen six months after operation. The testicle was apparently normal on palpation—no tenderness—no atrophy. Patient rides daily without discomfort—has no symptoms, though this exercise caused much pain before operation.

A casual search through the literature reveals no report of a similar case. The operative treatment of acute epididymitis of course has been mentioned frequently, but none of the authors has discussed this phase of the subject. Painful testicle following gonorrheal orchitis does occur, the patients often becoming neurotic and frequently returning without sufficient signs to explain their symptoms. Adhesions of the peritoneum following inflammatory processes frequently cause pain. The tunica is peritoneum also, and well supplied with nerves. Following an infection of this character, adhesions with pain might be explained on the same basis. This explanation is offered merely as a suggestion.

This case was presented to the Section in Surgery at the Buffalo Academy of Medicine in January, 1911. I wish to acknowledge the courtesy of Captain R. Davis, of the Medical Corps of the Army.

127 Allen Street.

ENDEMIC MALTA (MEDITERRANEAN) FEVER IN TEXAS WITH THE ISOLATION OF THE MICROCOCCUS MELITENSIS FROM TWO PATIENTS

SECOND PAPER

ERNEST R. GENTRY, A.B., M.D., AND THOMAS L. FERENBAUGH, A.B., M.D.
Lieutenants, Medical Corps, U. S. Army
[WASHINGTON, D. C.]

In 1905, Captain Charles F. Craig,[1] Medical Corps, U. S. Army, reported a case of Malta fever which had originated in the United States. The patient was a nurse in a hospital in Washington, D. C., where she contracted the disease, probably from nursing infected soldiers. In addition he reported nine cases in United States soldiers, who had become infected in the Philippine Islands. From the introduction to this communication by Captain Craig we quote the following remark:

> I am convinced that a careful study by use of the Widal test and the agglutination reaction with *Micrococcus melitensis*, of many of the cases of obscure continued fevers which are prevalent in this country, will result in the demonstration that Malta fever is by no means a rare disease in the warmer portions of the United States, and that many of the so-called anomalous cases of typhoid fever are, in reality, instances of infection with the organism of Malta fever.

During June, 1911, while stationed at Camp U. S. Troops, Del Rio, Texas, one of us (Lieutenant Thomas L. Ferenbaugh, Medical Corps, U. S. Army), had the opportunity of observing five cases of continued fever occurring in the practice of Drs. R. M. Scott and S. L. Boren of Del Rio, and after making agglutination tests, reported these as cases of Malta fever.[2]

Following the report of these findings to the Surgeon-General of the Army and the confirmation of the agglutination test in the bacteriologic laboratories of the Army Medical School, we were ordered to Texas with a field laboratory to determine, if possible, the identity and extent of this fever. The field laboratory was first located at Langtry, Texas, owing to the fact that four of the patients had been infected near that place, and it was desired to investigate more fully and confirm the earlier work of Dr. Ferenbaugh on these cases.

Shortly after arrival at Langtry, two of the patients previously seen entered on a relapse. This report is based on a laboratory and clinical study of these cases during this relapse.

July 21, patient, C. E. (Case 1 already reported) entered on his third relapse, with a temperature of 104 F. and with the same symptoms as during the previous attack.

On the evening of July 21, a blood-culture was made; 0.5 c.c. of blood was inoculated into each of two sterile broth and litmus milk tubes, each containing 10 c.c. of medium. After incubation at 37 C. for three days the cultures were plated out on glucose-nutrose-litmus-agar and the plates incubated for three days at 37 C. At the end of forty-eight hours about twenty very small, discrete, transparent, circular colonies had appeared on each of two plates, which were later completely identified as the *Micrococcus melitensis*.

July 23 a second blood-culture was made, and the blood inoculated into flasks of sterile broth. After four days incubation the cultures were plated out on glucose-nutrose-litmus-agar with the following results:

Quantity of Blood, c.c.	Amount of Broth, c.c.	Results ......
2.	50.	Pure culture of *M. melitensis*
.3	10.	Sterile
.3	10.	*M. melitensis*
.3	10.	Sterile

One-tenth c.c. of blood was inoculated directly on to the surface of each of two glucose-nutrose-litmus-agar plates with a sterile L-shaped glass spreader and incubated three days at 37 C. Both of these plates were sterile.

BLOOD-EXAMINATION JULY 23

Red blood-cells	4,200,000
White blood-cells	6,500
Hemoglobin	75 per cent.

Differential count, per cent (500 cells):

Polymorphonuclear neutrophils	45
Small mononuclears	47.4
Large mononuclears	6.4
Transitionals	1.2
Eosinophils	0
Mastzellen	0
Nucleated reds	0
Parasites	0

The temperature returned to normal July 28. The patient at the time of this report had been working at the goat camp for the previous two weeks and had suffered no further relapse. On July 29 0.75 c.c. of a centrifugalized specimen of urine was plated out on each of two glucose-nutrose-litmus-agar plates. After four days incubation the plates proved negative for *M. melitensis*. Chemical and microscopic examinations of the urine were negative.

CASE 6.—M. E., Langtry, Texas, aged 26, goat herder, brother of the four patients previously seen in Del Rio by Dr. Ferenbaugh. The patient had been working at the goat camp for three months before the onset of the sickness, and had been drinking goat's milk at the camp. He became ill June 14, 1911, with headache and pain in the back of the neck; ached all over; no definite chill; profuse sweating, especially at night; complained a great deal of eyes smarting; appetite fairly good, bowels constipated. The patient did not go to bed during the first attack of fever, but stopped work. The fever ran a mild course and returned to normal June 24. Temperature remained normal until July 19, when fever again returned. When seen at the Army laboratory at Langtry,

July 21, the patient had a temperature of 102.5 F., and complained of headache, loss of appetite, pains in joints, weakness, profuse sweating at night and insomnia.

July 23 a blood-culture was made, and 4 c.c. of blood inoculated into a flask containing 60 c.c. of sterile broth. After incubation for two days the culture was found to be contaminated with a rapidly growing acid-producing coccus, and although the culture was plated out repeatedly on glucose-nutrose-litmus-agar no colonies resembling the *M. melitensis* could be found.

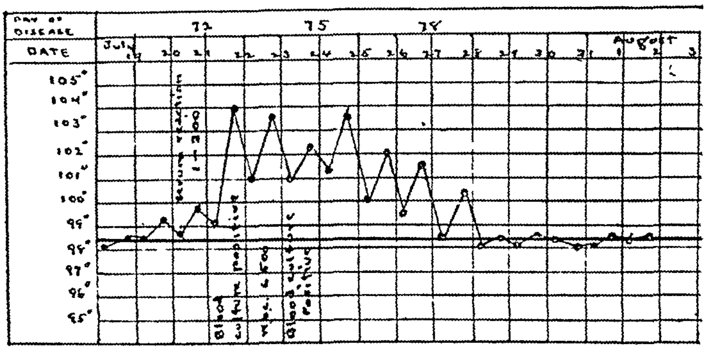

Fig. 1.—Chart showing temperature curve, blood-count and results of blood-culture in third relapse in Case 1 (C. E.).

July 29 a second blood-culture was made. The temperature at the time was 101.8 F. The blood was inoculated into flasks of sterile broth, which were incubated for four days and then plated out on glucose-nutrose-litmus-agar with the following results after three days incubation:

Quantity of Blood, c.c.	Amount of Broth, c.c.	Results ......
1.	100.	Pure culture *M. melitensis*
0.5	100	Pure culture *M. melitensis*
0.5	100.	Contaminated

Four-tenths of a cubic centimeter of blood was inoculated on to the surface of a glucose-nutrose-litmus-agar plate with a sterile L-shaped glass spreader. After two days incubation about twenty colonies of *M. melitensis* appeared on the plate.

Blood-serum on July 28 gave the following agglutination tests:

M. melitensis 1-80 dilution, positive in one hour.
Normal control 1-50, negative in one hour.
Bacillus typhosus, 1-50, negative in one hour.

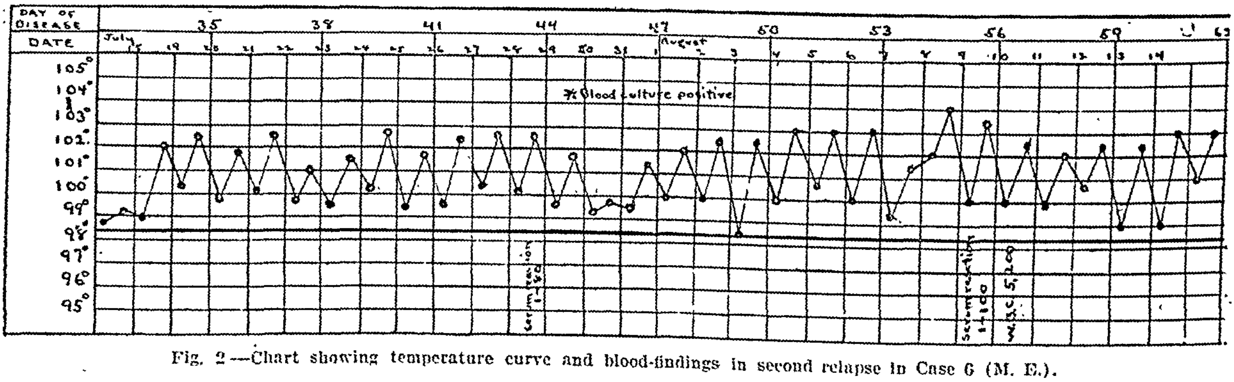

Fig. 2—Chart showing temperature curve and blood-findings in second relapse in Case 6 (M. E.).

BLOOD-EXAMINATION, AUGUST 9

Red blood-cells	4,390,000
White blood-cells	5,200
Hemoglobin	75 per cent.

Differential count, per cent. (500 cells):

Polymorphonuclear neutrophils	46.
Small mononuclears	47.
Large mononuclears	5.6
Transitionals	0.8
Eosinophils	0.4
Mastzellen	0.2
Nucleated reds	0
Parasites	0

Agglutination tests August 9 resulted as follows:

M. melitensis, 1-50 dilution, positive in 10 minutes.
1-100 dilution, positive in 30 minutes.
1-300 dilution, negative in 1 hour.
Normal control 1-50, negative in one hour.
Bacillus typhosus 1-50, negative in one hour.

The urine was repeatedly plated out on glucose-nutrose-litmus-agar, but was negative in each instance for *M. melitensis*. Chemical and microscopic examinations of urine were negative.

August 14, the patient was still very ill, the fever ranging from 100-102.5 F. daily. The patient complained of headache, profuse sweating, loss of appetite, pains in the joints and obstinate constipation. Physical examination showed enlarged liver and spleen with some tenderness over both. Abdomen slightly distended and some rigidity of the abdominal muscles was present; otherwise physical examination was negative.

Agglutination tests in the above cases were made both microscopically and macroscopically. Both methods gave identical results.

METHODS USED IN THE ISOLATION AND IDENTIFICATION OF THE MICROCOCCUS MELITENSIS

The organism was isolated by means of blood-cultures, which were made in two ways:

1. The ordinary method of drawing blood with a syringe from a vein in the elbow.
2. By the sterile capillary tube method of Zammit,[3] the blood being taken from the ear.

Both methods give good results. The Zammit method is especially useful in Malta (Mediterranean) fever, since the organism is present in small quantities of blood during the fever stage. Zammit isolated it from as small a quantity as 0.005 c.c. It is also valuable in field laboratory work where patients often refuse to permit the taking of blood from a vein.

Media.—Sterile broth in flasks, reaction + 1, was used as a preliminary enriching medium. The medium used for the isolation of the organism was a glucose-nutrose-litmus-agar[4] containing 1 per cent. each of glucose and nutrose and standardized to a reaction of + 1. The experimental work of Major Horrocks,[5] R.A.M.C., of the British Mediterranean Fever Commission, has shown that the addition of 1 per cent. nutrose to agar or broth greatly accelerates the growth of *M. melitensis* and also since the organism does not ferment glucose, the addition of this sugar tinted with litmus is of great service in isolating the organism from a mixed culture.

[4] Kolle and Hetsch: Die Experimentelle Bakteriologie und die Infektions-Krankheiten, Edition 2, Kultursmethoden.

[5] Horrocks: Reports of British Commission on Mediterranean Fever, Part 1, Article 1.

In obtaining the blood, strict aseptic precautions were observed in every case to avoid contamination. From 2 to 4 c.c. of blood were taken and inoculated into the broth-enriching medium in the proportion of one part of blood to not less than thirty parts of broth. The broth cultures were then incubated at 37 C. for four days.

In plating out these cultures, the liquefied glucose-nutrose-litmus-agar was poured into sterile Petri dishes and allowed to cool until the surface was well hardened. Several drops of the broth culture were then deposited near the center of the plate with a sterile pipette and then distributed over the surface of the medium with a sterile L-shaped glass spreader. Plates were then incubated for three days at 37 C.

After forty-eight hours' incubation there appeared, on the positive plates, a considerable number of small, round, transparent, colonies with a yellowish tinge and slightly granular center and presenting a typical "dew-drop" appearance by transmitted light. The colonies produced no fermentation of the medium and remained blue even after two weeks' growth.

The colonies were fished and the organism found to possess the following characteristics:

Morphology.—A small coccus, non-motile, emulsifies readily in hanging drop and exhibits the characteristic Brownian activity. It does not stain by Gram.

Cultures.—Growth on agar slants appears after three days incubation as small transparent colonies along the line of inoculation. In litmus milk after four days the milk becomes markedly alkaline without change in consistency of the medium. No fermentation in glucose.

Agglutination Tests.—Agglutinates readily with a specific immune serum at dilution of 1-1,000 in one hour.

Agglutinates readily with patient's serum at dilution of 1-200, in thirty minutes.

According to Major Horrocks,[6] "a microorganism which agglutinates with a specific animal serum in a high dilution, does not ferment glucose, renders milk alkaline without coagulation, may be justly regarded as the *M. melitensis.*"

The organism which we have isolated from these two cases of continued fever conforms to the foregoing criteria in every respect.

CONCLUSION

Endemic Malta fever exists in Texas at the present time.

We desire to thank Brigadier General George H. Torney, Surgeon General of the Army, for extending to us the opportunity for studying the identity and distribution of this disease. We also desire to thank Major F. F. Russell, Medical Corps, U. S. Army, and Captain Charles F. Craig, Medical Corps, U. S. Army, for much valuable advice and assistance.

Belladonna in Epilepsy.—The use of belladonna in epilepsy dates from the seventeenth century. It was recommended by Mardorf, in 1891, and later was a favorite remedy of Trousseau. Since the advent of bromid its use has become less general. It is of most avail in cases of *petit mal* and those complicated with nocturnal incontinence. The best results are obtained where it is given in conjunction with the bromids. The best preparation is the tincture in doses of from 5 to 10 minims.—E. L. Hunt in *Medical Record.*

THE CONTROL OF TYPHOID FEVER [*]

RICHMOND, VA.
Committee on Typhoid Fever

Typhoid fever is an acute, infectious and contagious disease occurring in man, and is caused by *Bacillus typhosus*. The typhoid bacillus depends for its perpetuation on multiplication in the body of man. The organism leaves the human body in the discharges from the bladder and bowel. All methods of control of typhoid fever must rest on the proper disposal of this material. If human excreta are prevented from reaching human mouths, typhoid fever will be entirely prevented.

In the United States, typhoid fever causes approximately 35,000 deaths, and incapacitates about 450,000 persons each year at their period of maximum earning capacity, thus causing an estimated economic loss of $150,000,000. The disease prevails practically throughout the United States. The application of the measures necessary for the control of typhoid is of paramount importance, not only on account of the large number of cases and deaths and the enormous economic loss resulting therefrom, but also because of the fact that these same measures will control a number of other diseases such as hookworm disease and diarrheas and dysenteries, and will render impossible the spread of Asiatic cholera.

THE TYPHOID ORGANISM

The typhoid organism is a motile bacillus, growing well on practically all laboratory media. Its resistance to heat, light and chemical agents is relatively low. Its normal abode is the human body, but under certain circumstances its life outside the body, as in water, sewage, soil polluted with human excreta, butter, or in shellfish may be prolonged for weeks or even months. Usually, however, its life outside the body is short. It resists drying as in dust or on clothing for considerable periods of time. The multiplication of the organism outside the human body takes place only under exceptional circumstances, and is not an important factor in the spread of the disease, except in connection with milk.

SOURCE OF THE INFECTION

The sources of the infectious material are the discharges from the human body. These may be from recognizable cases of the disease, from persons in the incubative or ambulant stages of the disease, from convalescents, or from the so-called chronic typhoid carriers. While the discharges from the bladder and bowel constitute the major portion of the infectious material, other secretions such as the tears, sweat, saliva or bronchial secretion of the patients may contain the organism. It also occurs occasionally in the pus from post-typhoid cold abscesses, and in the mammary secretion.

METHODS OF SPREAD

The usual portal of entry of the typhoid bacillus is the mouth. It reaches the mouth in food and drink, from infected fingers, possibly by infected dust, or by any other material infected with the specific organism.

---

[6] Horrocks: Reports of British Commission on Mediterranean Fever, Part 1, Article 3

[*] Report of the Committee on Typhoid Fever to the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Meeting, held at Los Angeles, June, 1911.

EPIDEMIC TYPHOID

While anything soiled with human excreta may act as a vehicle for transporting the infection from its source to the victim, water, milk or other foodstuffs are usually the vehicles in sudden epidemics or outbreaks of the disease.

Small streams or bodies of water usually not polluted may receive a relatively large amount of infectious material at one time, from a case or cases on the watershed, and may give rise to an extensive explosive outbreak. Streams or bodies of water usually more or less polluted with sewage may, by reason of changes in the conditions affecting the viability of the typhoid bacillus, or in the amount of infection they receive, become so heavily infected as to give rise to a sudden outbreak.

Wells and springs used by large groups of persons may become infected from seepage or from direct introduction of the infectious material, and thus give rise to an epidemic, more or less localized in character. Water in aqueducts, conduits or water mains may become infected through leakage.

Milk is a common vehicle for typhoid infection. The organism multiplies readily in milk. The milk may be infected by hands or flies soiled with human excrement, by being mixed with infected water, by the use of utensils which have been washed in infected water, or by being placed in infected bottles or other vessels.

Fresh vegetables, infected with human excrement used as a fertilizer, shellfish grown or "floated" in polluted water, or any food touched with hands soiled with human excrement, or placed in containers soiled with human excrement may give rise to epidemic typhoid.

ENDEMIC TYPHOID

In certain communities typhoid fever is continuously present. In such instances the infectious material may be *exogenous* or originating outside the community and be brought into it by a heavily polluted water-supply, milk or other foods more or less constantly infected. Even when the infection is not introduced from without in this way, a community may suffer from a continuously high typhoid rate due to *endogenous* infection or infection originating within the community itself. This type of typhoid has been called residual or prosodemic typhoid. Many factors contribute to the spread of endogenous typhoid fever. All depend on failure to exercise proper care in the disposal of human excrement within the limits of the community affected. These factors are: contact; surface wells and springs in the area affected; failure to diagnose, report and properly supervise cases of typhoid; improper handling of milk and foodstuffs; and the exposure of human excreta so that it may be scattered by flies or by other means.

The spread of typhoid fever depends on the same general factors in both rural and urban communities. In rural districts, the factors of water, milk and other foods are not so potent, as products of this kind from one source do not usually reach large groups of persons. Factors depending on flies, contact and similar means, on the contrary, are even more potent in the spread of typhoid in rural districts by reason of the almost universal use of the open surface privy.

INVESTIGATION OF TYPHOID FEVER

The investigation of the causation of typhoid fever necessitates a careful study into all the factors concerned in its spread. The investigator should be able to diagnose the disease, be acquainted with the methods of investigation, and have sufficient experience to interpret his findings.

Preliminary to investigation, all known cases, including abortive and mild cases of the disease, should be located. The diagnosis of a sufficient number of cases to determine the character of the disease should be made at the outset. Death certificates and reported cases should be tabulated and all cases reported by physicians as enteric fever, slow fever, fever, abdominal fever, typho-malaria, winter cholera, bloody flux, diarrhea, continued fever, malaria, nervous fever, or any febrile or intestinal complaint should be regarded as suspicious of typhoid until another diagnosis has been established.

In addition to the cases reported from physicians, other persons should be questioned as to suspicious cases occurring in their neighborhood and cases reported in this way should be promptly investigated. Records of hospitals in the community should also be examined.

As soon as the diagnosis is established and the cases collected, they should be investigated one by one. As far as possible each house in which a case has occurred should be visited and all information bearing on the case collected there. In order to secure accuracy, completeness and uniformity, it is desirable that some form of blank be used for the collection of this data. The blank should cover the following facts regarding the case: name, residence, color, sex, age, date the person took to bed, date of first symptoms, civil condition, school attended, church and Sunday school attended, occupation, how long at present residence, absences from home during month preceding illness, source of water used for drinking at home, at place of business, and water other than that of public supply drunk away from home during preceding month, source of milk used at home, other milk drunk, restaurants where patient has eaten during the month preceding, ice-cream eaten and its source, fresh vegetables and shellfish and their source, source of ice used at home, name of physician, exposure to other cases, cases in house previous to this, cases in neighborhood, cases at school or at place of business, etc., names of servants employed and residences of each, visitors at residence during month, general sanitary condition of premises, condition of well or spring, if any, condition of privy, if any, and screening against flies, condition as to isolation of cases and disinfection of discharges, screening of patient against flies, presence or absence of trained nurse.

Before any conclusion is drawn as to common sources of infection, all information collected about cases should be tabulated in convenient form so that all factors concerned may be seen together. A convenient method is to place the names or numbers of the cases in a vertical column at the left side of the sheet, other vertical columns being ruled for the various factors involved. The information regarding any one case is thus in a horizontal line, while the information regarding any one factor such as milk, contact, etc., is in the vertical column. A separate sheet should be ruled for the milk-dealers, their names being in the vertical column to the left; other vertical columns should be ruled, one for each day of the epidemic. Cases can then be spotted against the milkman on the day of their occurrence. All tabulations should be made in reference to the day on which the patient takes to bed. The cases should be plotted by days, giving the chronologic curve of the outbreak. If a map of the community is available or if one can be made, the cases should be spotted on it according to the point of origin. Spots or tacks of different colors may be used on this map to indicate different facts regarding the cases.

A study of the charts and maps so prepared may direct the investigators' attention to some factor or factors, as being most probably responsible for the spread of the disease. Certain factors can usually be eliminated as a result of this preliminary study. Attention should then be focused on those factors which, apparently, might be responsible. All clues and leads should be followed up until all information bearing on them has been collected. The investigator should retain an open mind throughout the study and should always remember that other minor factors may contribute to the spread of the disease within limits, even though the great bulk of the cases may be caused by some great general factor.

WATER OUTBREAKS

In order to direct intelligently the field investigation which must be taken up after the cases have been inspected, the investigator should recognize the general features of epidemics due to different causes. If the preliminary study shows all or practically all the patients to have used habitually any common supply of water, investigation of the conditions surrounding the water-supply should be made at once. In a sudden outbreak, especially during the winter months, in a community previously practically free from the disease, unless there is strong evidence that milk is responsible, water should be assumed to be the cause of the outbreak until proved otherwise. In all instances in which the users of any common water-supply seem to suffer more severely than others, suspicion should be attached to the water.

A sanitary survey of the water-supply should be instituted at once in all such instances. On small watersheds, the entire area should be gone over as thoroughly as possible to find any existing points of obvious pollution, and to locate actual cases of the disease which may have furnished the infectious material. Where larger streams are used, all sewage outfalls should be located, the intake for the water-supply examined, and all information possible regarding pollution further up stream collected. Currents, ice, freshets and other factors of flow should be determined. In communities using water from ponds and lakes, points of pollution along the shore should be determined, sewer outfalls located, and currents and prevailing winds should be taken into consideration. Where wells or springs are used they should be carefully inspected and nearby points of pollution, sewer lines in the neighborhood or local pollution about the mouth of the well or spring should be determined. All geologic facts bearing on the supply of such springs and lakes should be collected and considered. Pumping stations, filter-plants, storage reservoirs and all parts of the distributing system should be examined as completely as possible. Breakdowns, overflows, shortage, supplementary supplies, and emergency systems for fire protection should be determined and recorded.

While sanitary inspections usually give the most important information about the pollution of a water-supply, valuable additional information may be obtained in many instances from the results of careful chemical and bacteriologic work. Whenever possible, samples should be collected and examined at every stage in the passage of the water from its source to the consumer. Vended water-supplies in use in the community should be inspected and examined in the same way as public supplies, if there is any suspicion of their being responsible for the outbreak.

MILK OUTBREAKS

Indications pointing to typhoid infection from milk usually appear early in the investigation. The fulminant character of the outbreak in which the maximum number of cases per day appears almost immediately, the distribution in certain sections of the community, and the high incidence of the infection among users of milk usually give the investigator a clue. The first step in the investigation of evidence should be the tabulation of all milk-dealers supplying the community, with the approximate number of gallons per day distributed by each. Those dealers showing a disproportionately large number of cases should be investigated first. Every step in the course of the milk from the cow to the consumer should be scrutinized. In instances in which the dealer handles milk from only a few farms, this is relatively a simple matter, involving a trip to the dairy and dairy farms, the inspection of all employees, collection of information as to the health of all employees and to their association with the sick, particularly those recently employed, discharged or leaving on account of illness, also an inspection of water-supplies used for cooling or cleaning of utensils or cans. The methods of transportation, possibility of infection during transportation, the city milk depot, its employees, methods, equipment and water-supplies, and lastly the driver of the individual wagon and the methods of vending must be taken into account. Bottling and the possibility of infection from bottles coming from houses in which the disease exists should be considered. In investigations of the possibility of infection of milk by handling, bacillus-carriers should be constantly kept in mind.

OTHER FOODS

The determination of the influence of foods other than milk in the transmission of typhoid is usually a matter of great difficulty. Other factors should be eliminated as completely as possible before attention is focused on this point. In instances in which fulminant outbreaks of typhoid fever occur among those who have partaken of certain articles of diet in common, each item of the menu should be traced to its source, and all persons concerned in the vending, preparation and serving of the various articles of food subjected to careful examination as to their sanitary history. In addition it should be determined exactly what articles on the menu were eaten by each person affected. In this way the infected article may be incriminated. Chemical or bacteriologic examination of food remaining from the meal, or of like articles of food from the same source as those suspected, may furnish additional evidence. The present methods of isolating typhoid bacilli from foodstuffs are difficult and uncertain. Furthermore, infection of foodstuffs is often transitory, occurring at intervals, and the life of the typhoid bacillus in most foods is so short that it may not survive for the time elapsing between the infection and investigation. For these reasons failure to recover the organisms should not negative strong epidemiologic evidence.

SPREAD FROM ENDOGENOUS INFECTION

When the introduction of exogenous infection through water, milk, or other foods is eliminated from the problem, other factors must be considered. The determination in any community of the means of spread of typhoid fever arising from sources within the community itself is, as a rule, a matter of great difficulty. Many factors varying in degree of their operation are involved. In addition to direct personal contact with the case of typhoid, indirect contacts, varying in degree and often devious and obscure in their course, undoubtedly contribute to the spread of the infection. Any foodstuff or any material handled by human beings so as to become soiled to the slightest extent with human excreta may act as a link in the chain of indirect contact. Hands so soiled may serve to infect bread, fruit, milk or other foods which may in turn carry the infection to an indiviual or a number of persons. Flies which have had access to infectious material may act as distributing agents. Surface wells and springs locally polluted may give rise to few or many cases of the disease among the persons using them.

Due to the multiplicity and complexity of the factors concerned in the spread of typhoid fever from endogenous infection, a study of cases resulting from such infection seldom presents the characteristic and striking features presented by a study of cases from exogenous infection. A careful study of all cases in the community under consideration is always necessary. In some instances this study must be prolonged over a considerable period before reasonably definite conclusions can be reached. In addition to study of individual cases, and such studies of the water, milk and other food-supplies as are necessary to eliminate them as vehicles for the transportation of infection, the general features of the disease in the community should be given careful consideration. The facts regarding the prevalence of the disease for as long a period of years as accurate statistics are available, should be carefully compiled, charted and studied. The number of cases and deaths for each month of the years for which records are available, should be charted, and the average morbidity and mortality rates for each month should also be charted.

A chart showing the relation between the average monthly death-rate and the average monthly mean temperature for the same period of years should be prepared. In communities in which typhoid fever is due largely to endogenous infection, the typhoid curve follows closely the temperature curve, taking into account the time elapsing between the infection and the death of the patient. For communities using a heavily polluted water, peaks in the typhoid curve during the winter and spring months are frequently higher than the crest of the summer curve.

A strikingly seasonal (summer) prevalence of typhoid fever in a community should not be taken, however, as a positive indication that the disease is due entirely, or even for the greater part, to endogenous infection; because coincident with the warm summer weather there may be an increase in the number of cases in the surrounding country, with a consequent increase in the amount of exogenous infection introduced through foodstuffs which have become infected at their farm sources.

The geographic distribution of the cases in the community is sometimes of significance. There may be a well-marked tendency toward concentration of cases in and around insanitary areas. It should be borne in mind, however, that even when the disease is due almost entirely to endogenous infection it may be generally distributed over a large community.

The chronologic distribution is frequently suggestive. Scattered cases appear at intervals, gradually increasing in number and reaching a maximum usually toward the end of the hot season, then declining slowly to the winter normal. This is usually in striking contrast to the sudden explosive character of an exogenous outbreak.

If the sanitary survey of the community reveals the existence of a large number of open privies or of other insanitary practices giving rise to wide-spread excretal contamination, it may be assumed that typhoid fever is spread as a result, and the finding of such conditions constitutes important corroborative evidence of endogenous infection.

A conclusion that typhoid fever in any community is due largely to either endogenous or exogenous infection should be drawn only after an exhaustive study of all the facts available. In practically every community in which typhoid fever prevails both types of infection are operative, their relative proportions varying from time to time. Measures for the restriction of typhoid fever in any community must therefore comprehend all factors concerned in the distribution of both endogenous and exogenous infection.

THE PREVENTION OF TYPHOID FEVER

While means for the prevention of typhoid fever vary according to local and other conditions, certain fundamental procedures are necessary in every case.

An adequate supply of water of good sanitary quality for domestic use is, of course, absolutely necessary. The work of furnishing such a supply is usually left to engineers, but sanitary considerations in connection with any supply should be paramount. Under emergency conditions, a water-supply, even if known to be polluted, may be rendered safe for use by disinfection with hypochlorite of lime. Supplies obtained under conditions indicating pollution and used without filtration should be furnished with auxiliary plants for the addition of hypochlorite of lime to the water. Where public supplies are not available, as in small towns and rural districts, all wells and springs should be supervised to secure such construction and care as will prevent pollution.

An adequate sewerage system, reaching every part of the community, should be constructed whenever possible, and every closet should be connected with it. Soil pollution should be prohibited under penalty. Where water carriage of sewage is impossible, all privies should be built and kept strictly in accordance with sanitary principles; to retain the excrement in a water-tight receptacle, screened against flies, until it is removed under official supervision. When possible, the material from the privies should be cremated. When this is impossible, it should be mixed with a disinfectant solution and buried as far from human habitations and important watercourses as possible. It should never be used for fertilizer on any garden or truck farm.

Milk production should be under constant and rigid supervision. All dairies and milk depots should be frequently inspected, the greatest possible degree of cleanliness should be insisted on, and all cases of sickness on a dairy farm should be promptly reported to the health authority and immediately investigated. When indications point to infection of any milk-supply, the consumer, rather than the producer, should always be given the benefit of the doubt. No large milk-supply can be regarded as safe, in view of the likelihood of frequent accidental infection, unless subjected to efficient pasteurization under official supervision.

Accurate supervision of all cases is of the greatest importance. This should include visitation of every case as soon as reported, with collection of epidemiologic data, instruction of the family as to necessary precautions, particularly in regard to disinfection, free supply of disinfectants to the poor, provision for screening of all cases against flies, and revisitation as often as necessary to secure proper care of each case. The visiting nurse is of great value in this work.

Provision should be made for prompt diagnosis of all suspicious cases by laboratory methods. The blood-culture is recommended for this purpose.

Fly prevention by removal of filth and garbage and legal control of stables, requiring screening of manure pits and weekly removal of manure should be practiced.

Garden truck and fruits should be protected as far as possible by screening against flies, and cleanliness in all shops and other places where human food is stored or handled should be required. The use of human manure for fertilizer on truck gardens should be absolutely prohibited. Restaurants, soda fountains and ice-cream factories and depots should be frequently inspected and cleanliness required.

Popular education regarding the nature, cause and means of spread of typhoid fever, particularly with reference to spread by contact with the case and by fecal contamination, should be carried on until every citizen is acquainted with the facts about the disease.

In rural districts the construction and maintenance of a sanitary privy on every farm, the total abolition of the surface privy, the proper construction and care of wells and springs, and the education of the people as to the contagiousness and necessary means for preventing the spread of the disease are the essential measures. Education is the first essential.

Vaccination against typhoid fever by inoculations with killed cultures of typhoid bacilli seems to confer a marked immunity to the disease. While the duration of this immunity has not yet been definitely determined, the results of experiments with the agglutination of the blood of inoculated persons would indicate that the immunity has a duration of less than one year. It should be borne in mind, however, that the duration of the immunity may not coincide with the persistence of the agglutinating reaction in the blood. This has still to be determined. The reaction from the inoculation is in most cases slight, and the value of the protection has been thoroughly demonstrated by its use in military forces. These facts would seem to warrant a more general use of the method in those particularly exposed to the infection, especially physicians and nurses. Its value in the face of an epidemic has still to be determined.

In conclusion, the prevention of typhoid fever in the United States to-day depends on an improvement in the present methods of disposing of human excreta. Until all the people can be taught that the most dangerous material with which they come in contact in their daily lives is filth from human bodies, and until their sanitary habits are so changed that human filth is prevented from reaching human mouths, the prevention of typhoid fever cannot be consummated.

The necessary brevity of this report has prevented a fuller discussion of many questions into which the committee would otherwise have gone at length.

The report is a condensation of facts and views from many sources and your committee has not deemed it wise to attempt to give individual credit for them.

The views expressed in the report regarding typhoid fever from infection originating within the affected community are based largely on work done in the cities of Washington, D. C., and Richmond, Va. The committee feels that it should acknowledge its obligation to Dr. E. C. Levy, Chief Health Officer of Richmond, Va., for much of the work on which these views are based and for much assistance in clearly defining the distinction between the two types of infection in any community — that originating without and that originating within the community itself.

HOW TO COLLECT OLD MEDICAL BOOKS IN EUROPE

WHERE TO GO AND WHAT TO LOOK FOR *

FIELDING H. GARRISON, M.D.
AND
FELIX NEUMANN
WASHINGTON, D. C.

There are physicians who not infrequently apply to themselves what, it may happen, is one of their own favorite prescriptions — a summer vacation in Europe. To such, a few hints as to ways and means of locating rare medical books while abroad may not come amiss, while it may perhaps interest the returning traveler to survey a few actual or hypothetical experiences.

We will assume that our traveler, if not interested in the whole history of medicine, or at least a specialist, is at any rate sportsmanlike enough to care something about the classics in his favorite branch of medicine. To one of this stamp Europe is indeed the Happy Hunting Grounds — the most favorable haunt for the medical book-lover. On the Continent there is always an even chance of picking up some little treasure-trove of European medicine or even one of the earlier medical Americana for a song. But, as with hunting and fishing, there are more ways than one, so success oftenest comes to him who shuns "the madding crowd's ignoble strife." Where there is more competition among buyers than among sellers, prices are sure to be high and let no one fancy that the larger antiquarian bookstores in cosmopolitan centers will let anything go for less than it is worth. In an interesting talk before the Medical Library Association in the spring of 1909, Sir William Osler emphasized the point that, on account of the growing interest of medical book-fanciers in rare first editions and quaint folios, such things are becoming practically inaccessible by reason of the prohibitive prices put on them by antiquarian booksellers. Reasonable figures, it seems, can only be had at some occasional auction sale or in out-of-the-way places in Italy. To illustrate this, he cited an experience of a copy of the "Inventum Novum" picked up for a lira, when a western colleague who was also an admirer of Auenbrugger had just paid $100 (about 500 times as much) for the same classic in Germany. This is, of course, an exceptional piece of luck, yet it illustrates the value of frequenting the haunts of the *Kleinstädter* — the little stalls about Paris, the English cathedral and seaport towns, some quaint old city of the Low Countries, the little places nestled in the Swiss or Tyrolese Alps, the charming old towns of the Fatherland, famous in civilization and learning, and, above all those Italian cities of lesser rank, which Renan thought still "aglow with infinite glory"— Florence, Siena, Perugia, Padua, Milan, Turin. Let neither Venice nor the devious by-ways of the Eternal City be forgotten, nor Vienna and the Slavic and Scandinavian university towns. It is in the modest obscure book-stalls of places like these that one can buy to greater advantage, sometimes making remarkable finds at prices four or five times less than the experienced antiquarian would sell them for.

As the true traveler is not he who rushes from pillar to post, annihilating space and time in his mad effort to see everything at once, but rather he who is inclined to "loaf and invite his soul," to saunter, to *flâner* and to absorb the atmosphere of some beloved place, so there is a gentle art of book-buying as well as of book-selling, the rudimentary features of which are known to every true bibliophile. We can only deal in glittering generalities, but those of the true cult inevitably get the browsing habit. As in bazaars in the far East, shopping is always a sort of social diversion, so the book-lover *pur sang* will never ask for a coveted volume pointblank, for, if the dealer happens to be one who has a sliding scale of prices, he is sure to profit by so naïve an interest, especially if his prospective customer is perceived to be a foreigner. As Balzac says: "Too much confidence diminishes respect, while others take advantage of excessive enthusiasm." If time permits, it is better to spar for points. Look as innocent as possible, and when the zealous bookseller comes smilingly forward, simply say that you want to look around a little. Left to your own resources walk from shelf to shelf, addressing to the bookseller now and then some question which will bring you nearer your goal. Perhaps, like the unfortunate antiquarian in Henry James' remarkable study "The Bench of Desolation," your dealer may have a fine feeling for literature itself. In this case you can safely chat with him about the desired volume, and it would be a very poor bookseller indeed who failed to produce it under these conditions along with some others. He will, in fact, show you these books in the spirit of the hidalgo in "Hernani"—*J'en passe et des meilleurs.* You examine them at leisure and finally say, in passing, that while it is not exactly of great interest to you, you might buy this volume if it does not come too high, or else simply price the books indifferently one by one. The dealer, happy that he is, after all, about to make a sale to the stranger, names a moderate price, and the purchaser walks away in the happiest frame of mind. On the other hand, a bookseller who nags his prospective customers with his importunities, however polite or well-meant, is not likely to attract them. It is an unwritten law of human nature that those who make social or other advances too rapidly usually turn out to be suspicious acquaintances and a fair standard of self-respect, for men and women alike, is summed up in the famous inscription over the gateway of Krupp's gunfoundry at Essen: "Those applying for permission to see these works may expose themselves to a refusal." As a rule, however, such defensive tactics are seldom necessary with the gentle antiquarian who is too frequently of a retiring, if not of a negative, disposition.

* From the Library of the Surgeon General's Office.

* For reasons of space, a "miniature Baedeker for medical bibliophiles," prepared to accompany this article, is here omitted, but is given in full in the authors' reprints, which will be sent on request by the authors or by THE JOURNAL, on receipt of a stamped and self-addressed envelope

In the matter of prices in general, whether printed in a catalogue or given by word of mouth, we should say that, provided one can afford it, the price asked for any good book is seldom too much. It is always well to remember, too, that what seems a large sum of money, as given in francs, marks, lire, crowns or roubles is, after all, not so much in United States money or as compared with American prices for the same book. The genial Autocrat once described himself as springing like a tiger on some coveted volume and the real ardor of the chase lies not so much in driving a bargain as in getting what one wants by the hunting instinct.

In seeking for rare medical books it is quite necessary to have the collector's *flair* for the quarry—to know what to look for. Yet, even when this condition is fulfilled, a possible purchase must still depend on two determinants: the extent of the purchaser's inclination and the length of his purse. Readers of Goethe's autobiography will remember how he advises the connoisseur in painting to buy the best pictures of his own period rather than old masters because, for the same or even less money he can in this way build up a collection which will become choice and rare enough in his own life-time. This is even more true of the medical classics for, as we have said, prices for the older books are even now so prohibitive that they can only be collected by book-clubs and libraries or else by the few physicians who may be accounted "wealthy" in the financial sense. At a time when American enthusiasts will pay as much for the Baltimore edition of Edgar Poe's maiden efforts in verse as they would for the first folio of Shakespeare ($2,900 in two instances), it is hardly likely that the greater classics of medicine—the Greeks, Vesalius, Paré, Harvey, Sydenham—will go a begging, unless there should be some unimaginable world-slump in prices. The old Greek and Roman classics are, in most cases, fine specimens of the work of the great Renaissance printers, and many of these are therefore the *ultima Thule* of the collector. As Osler has said, "An Aldine here and there, a few fine parchment-bound Juntas, an Oporinus or a Froben in the original boards and stamped pigskin, a fine Paris Stephanus, an Elzevir or a Plantin, give tone to the shelves, just as do the Stuarts and Copleys to the dining-room in an old mansion."[1] The antiquarian dealers know this and charge accordingly. Some of these specimens of fine printing, however—the Elzevirs in particular—have greatly decreased in value of late years and are consequently more easily obtainable by those who fancy them, while the books of the English printers of the sixteenth century—Wyer, Pynson, Copeland—have increased in value from fifty to a hundred fold on account of their present scarcity, originally due to the destruction of so many of them during the Civil Wars of England and in the Great Fire of London in 1666. For example, the different imprints of Linacre's translations of Galen and many of the English anatomical classics of the post-Vesalian period are exceptionally hard to come at, and, in each case, like the bronze in Browning's poem, "esteemed a rarity." Should any collector be lucky enough to bag any piece of early printing, English or other, he may remember that it is quite immaterial if the book has no intrinsic value in itself. Any specimen of early printing or of a famous printer has a bibliographic value which determines its price irrespective of its intrinsic value. For this reason, we repeat, the books most likely to be within the average collector's reach are those of the eighteenth and nineteenth centuries and, of these, stray "bargains" at stalls will usually be in pamphlet form (within a hundred pages in size). By sheer luck a collector might happen on a Rösslin, a Cornaro, a Fracastorius, a Paracelsus, with its flamboyant title-page in red and black type, an Athanasius Kircher or even a Wepfer on apoplexy offered at a reasonable figure somewhere on account of its small size or shape, and classics of these dimensions increase in number as we approach the modern period. The small-sized book, like the short story, the lightning express, the telephone, wireless, the motor-car, the airship, predigested foods, tabloid preparations, heart-to-heart talks and saltatory evolution per social uplift is one of those frequently unattainable ideals of modern life which illustrate Maupertuis' principle in mechanics: that we aim to get at anything or to get out of any difficulty by the shortest possible cut. It is in the eighteenth century that we begin to find the little classics or *Kleinmeister*—things like Fothergill on diphtheritic sore-throat (1747), Caspar Friedrich Wolff's "Theoria generationis" (1759), Auenbrugger's "Inventum novum" (1761), Sigault on symphysiotomy (1777), Pott on spinal caries (1779), Mesmer on animal magnetism (1779), Withering on the foxglove (1785), and Jenner's different pamphlets on vaccination. In the nineteenth century the number of these pamphlet classics begins to increase apace, following the modern tendency toward specialization, and the specialist will naturally keep his eye open for the famous monographs on his particular subject. We may expect the anatomist to look not only for the numerous post-Vesalian pamphlets of the seventeenth century but also for the essays of Cooper, Wrisberg, Meckel, Lieberkühn, Zinn, *hoc genus omne,* for the beautiful title-page of Lorenzo Bellini on the structure of the kidneys (Florence, 1662), and for Goethe on the intermaxillary bone (Jena, 1786); the adept in finer anatomy for Schwann (1839) and Schleiden (1842), Gerlach (1858), Max Schultze on protoplasm (1867), Walther Flemming on cell division (1882), Golgi (1885), Ehrlich on intravital staining (1886), and Ramon y Cajal's "Nuevo concepto" (1892). The physiologist might begin with the English classics on respiration and keep in mind a long list of attractive desiderata of small size, including Galvani on animal electricity (1792), Sir Charles Bell's "New Idea" (1811), Marshall Hall on reflex action (1833), Beaumont on the gastric juice (1833), Purkinje on ciliary motion (1835), Helmholtz on the conservation of energy (1847), the epoch-making monographs of Claude Bernard, Pflüger on electrotonus (1859), Marey on the sphygmograph (1860), Fritsch and Hitzig on cerebral localization (1870), Hering on facultative organic memory (1870), or Bayliss and Starling on the chemical regulation of the secretions (1904). The clinician may reflect that there is probably only one copy of Parkinson on the shaking palsy (1817) in the United States, and perhaps only two to be found in any English library;[2] he will know why Heine on infantile paralysis (1840) or Currie (1797) and Brand (1863) on hydrotherapy in typhoid are so much worth having nowadays and why the second edition of Laënnec would be quite as valuable a possession as the first. The surgeon will naturally value the original pamphlets on anesthesia, or Lord Lister's original paper on antiseptic methods (1867), or Esmarch on hemostatic bandaging (1873); the obstetrician and gynecologist will probably hold in especial esteem Paré on podalic version (1555), Deventer on pelvic deformities (1701), Holmes (1842) and Semmelweis (1861) on puerperal fever, Simpson on chloroform (1847), Marion Sims on vesicovaginal fistula (1853), Noeggerath on latent gonorrhea (1872), Parry on extra-uterine pregnancy (1876), Sänger on Cesarean section (1882), Credé on infantile conjunctivitis (1884), or Tait on pelvic hematocele (1888). The ophthalmologist will have a long list of "real values," ranging from Bartisch's "Augendienst" (1583), Kepler's "Paralipomena" (1604), Scheiner's "Oculus" (1619), Descartes' "Dioptrics" (Elzevir of 1644) to Brisseau (1706) and Maître-Jan (1707) on cataract, Dalton on color-blindness (1794), Young on astigmatism (1801), Helmholtz on the ophthalmoscope (1851), Snellen on test-types (1862) or the Sydenham imprint of Donders on accommodation and refraction (1864). The throat specialist will not forget the three pamphlets of Manuel Garcia (1855), Türck (1858), and Czermak (1858) on laryngoscopy, Bouchut and Trousseau on laryngeal intubation (1858) and the earlier reprints of O'Dwyer. The expert in medical jurisprudence will, of course, have a lively interest in the Caroline Criminal Constitutions (1533) and the little treatises of Codronchi (1597), Fedeli (1602) and Zacchias (1621).

---

[1] Bull. Med. and Chir. Fac., Maryland, Baltimore, 1909, i, 251.

There are some medical books of exceptional rarity such as the early tracts on syphilis, Bagellardo on pediatrics (1472), Grassi on eye diseases (1475), the Florentine *editio princeps* of Celsus (1478), the booklet on personal hygiene which Moses Maimonides wrote for the use of Saladin (Florence, 1478), Mattioli's commentary on Dioscorides (1544), the first edition of Sydenham's "Schedula Monitoria" (1666) and Sanctorius' commentary on Avicenna (1625) concerning which Dr. Weir Mitchell relates that it took Quaritch seven years to find him a copy.[3] Chances of finding these are variable. As Dr. Billings has remarked,[4] a collector of to-day is as likely to pick up Gordon's "Lily," Gaddesden's "Rose" or any of the incunabula listed by Hain as the early American tracts of Thacher, Boylston and Waterhouse on small-pox. Many of the best-known classics of more recent times, such as Daviel on cataract extraction (1753), the original Latin of Wolff's great monograph on the development of the intestines (1764-6), Lavoisier's discovery of oxygen (1775), Parry on exophthalmic goiter (1786), McDowell on ovariotomy (1816), Wöhler's synthesis of urea (1828) or Gregor Mendel on plant hybridity (1865) are buried in the pages of rare periodicals.

A special class of books which will grace any public or private collection is that which includes the best specimens of anatomic illustration, from the imposing woodcuts of Vesalius and Stephanus and the splendid copper-plates of Casserius, Bidloo, Ruysch, Mascagni and Albinus, down to the spirited steel engravings which Anderloni made from Scarpa's pen-drawings, or the self-illustrated "Dissections" of Sir Charles Bell. In this class one might include the actual anatomic works of great artists—the folios of Leonardo da Vinci's drawings in red chalk (1898), Albrecht Dürer on human symmetry (Nuremberg, 1532), Rubens' "Théorie de la figure humaine" (1773), John Flaxman's "Anatomical Studies," (1833), and perhaps even a specimen or two of those curious short-hand notations of human anatomy from the pencil of Rodin. One rare and valuable example of pathologic illustration, the "Selecta Praxis Medico-Chirurgica" of Alexander Auvert (Paris, 1856), has a unique interest. It consists of a series of masterly delineations of disease, executed partly by means of colored line engraving, partly in stipple retouched in watercolor, and is much esteemed, not only for its accuracy of detail, but particularly as a wonderful example of illustration in colors. The only copy of the first edition in the United States is to be seen in The Library of the Medical and Chirurgical Faculty of Maryland.

A word about Spanish medical books, in which most medical libraries are known to be sadly deficient. Spain may seem as virgin soil to the collector, yet the medical books printed in Spain and Portugal before 1500, and even up to 1550, are of such extreme rarity and their value so well-known even to the obscurest Spanish bookseller, that there is little chance of finding them, while the modern medical literature of Spain, always excepting the writings of Gimbernat and Ramon y Cajal, has nothing of more than ordinary interest. Of especial value are the surgical treatises of Julian Gutierrez (1494), Juan de Aviñon (1545) and Francisco Arceo (1574), Valverde's "Anatomy" with its characteristic copperplates (1559) and Joseph d' Acosta's "Historia natural y moral de las Indias" (1590), which contains the first account of mountain sickness. A find which might dignify any surgeon's collection would be a possible copy of the rare Spanish translation of Lanfranc's "Cirurgia," published at Seville in 1495. As a specimen of splendid typography it is comparable with a black-letter Chaucer.

Collecting old books in midsummer might be likened to the almost outworn boyhood diversion of looking for primitive stone implements over tilled fields in the springtime. As the farmer's ploughshare used to turn up a new crop of Indian arrow-points and stone axes regularly each succeeding year, so the owner of valuable books, is for various reasons, often disposed or obliged to get rid of some of them as summer approaches. A good rule is, always to look for a book highly valued in a given country in some other country. For example, Schoepf's "Materia medica Americana" (Erlangen, 1786), of which we know of only three copies in America, might very well turn up somewhere in Germany at a moderate price.

It is hoped that these random notes may emphasize a few bibliographic values which the specialist, from his deeper knowledge, will not regard as impertinent.

THE USE OF SALICYLATES IN RHEUMATISM *

ALEXANDER LAMBERT, M.D.
NEW YORK

We frequently hear dissatisfaction expressed concerning the treatment of rheumatism with salicylates. This dissatisfaction seems to arise from several causes, either because every ache or pain or morbid process which occurs in the muscles or joints will not react promptly to salicylates, or because the patient cannot tolerate the enormous doses administered, or that even in spite of large doses up to tolerance, certain lesions such as the cardiac lesions of true rheumatism, are not controlled or prevented with facility equal to that by which the pain and swelling of the joints are controlled.

Let us consider for a moment the various treatments that were used before salicylates, in 1875 and 1876, were first used for rheumatism. After having tried the enormous bleedings for depletion, and terrific purgation by mercury, and the various antiphlogistic ideas for which veratrum viride, aconite and antimony were given in large doses, and having frankly realized that these did harm rather than good, the profession settled down to either doing nothing at all and treating symptoms as they arose, or giving the so-called alkaline treatment with potassium bicarbonate, which certainly did not harm the patient as many of the other forms of treatment had done, but which, on the contrary, seemed to show a distinctly beneficial effect, for in fact under this treatment there was and still is less cardiac involvement than under any other single or uncombined treatment.

Today, outside of some form of salicylate treatment, the alkaline treatment remains the most effective. The men who first tried the salicylate treatment had seen many methods tried and pronounced a failure, and after thorough trial they were forced to the conclusion that the salicylate treatment shortened the period of pain and fever in rheumatism. Maclagan said that the duration of the pain and suffering was the same number of days as formerly it had been weeks.

One great difficulty from which the profession is slowly emerging is the lack of differentiation made between true rheumatism, which will respond to some form of salicylates, and the various other forms of arthritis which occur, as gout, tuberculosis, the infected arthritis accompanying gonorrhea and scarlet fever, rheumatoid arthritis, and the infected arthritis of unknown origin, such as Still's disease, affecting the smaller joints; these are all classed together as rheumatism and often treated alike. "He who diagnosticates well, will cure well," was never more strikingly illustrated than in the benefits of a correct diagnosis in the various forms of arthritis, and the proper treatment for each varying morbid process. Salicylates will not disinfect the pus of a scarlatinal joint. They will not immobilize and clean out a tuberculous joint. They will not act as a tonic or as an alterative and build up a depleted body and help it overcome the disintegrating processes of arthritis deformans. They may quiet the pain, but they will not subdue the inflammation in the spindle-shaped joints of the fingers in the acute arthritis of unknown origin. They may stop the pain in gout and, with rest in bed and free purgation, the gouty attack pass by, but we cannot expect their full, rapid and beneficial action except in the case of genuine rheumatism.

By rheumatism is meant here that inflammatory process of the larger joints which in childhood is so frequently accompanied with cardiac involvement, and in adult life shows some form of cardiac involvement in over 50 per cent. of those affected. Monarticular rheumatism is exceedingly rare, and in true rheumatism the small joints of the fingers and toes are involved with equal rarity. In this article the symptom-complex of the inflammation in the large joints with or without cardiac involvement is alone referred to as rheumatism.

If we confine ourselves to this conception of rheumatism, I am sure that we shall find some form of salicylates which will act beneficially; but simply because salicylates will act beneficially we are no more justified in treating patients suffering from rheumatism in an absolutely routine way than we are in any other disease. The human intestine is not a test-tube, although often treated like one, and a human organism has its distinct tolerances and intolerances for the different forms of salicylates as distinctly as it has for other remedies.

Most patients are easily irritated by salicylic acid and their stomachs soon reject it, yet these same patients will readily take sodium salicylate with no disturbance. Some patients cannot take sodium salicylate, and yet they tolerate oil of wintergreen in large doses and rapidly respond to it. In other patients I have seen salol and salicin act well, when other forms of salicylates would not, and certainly in children and in the aged, salicin is recognized as the form which is the least depressing and from which the most benefit seems to be obtained.

Aspirin has lately come into vogue and is highly praised by some authors, and yet in my own hands the result from it in rheumatism has been very disappointing. Synthetic methyl salicylate is to be avoided for internal use, and should only be used externally, and yet oleum betulæ (the oil of sweet birch) contains the methyl salicylate in the natural form, and is one of the most active and broadly tolerated with the least toxic symp-

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

toms of all the salicylates, and it seems a generally accepted fact that the natural salicylates are less irritant than the synthetic.

Synthetic salicylic acid is usually formed from phenol, and the orthosalicylic acid is the one used medicinally. The meta-acid is therapeutically inert, and the para-acid is sometimes present to the detriment of the results obtained, for it is distinctly more toxic than the ortho acid. At times all the phenol is not converted into salicylic acid, and one often wonders when reading of the cases of toxic action of collapse with failing respiration, whether it is not a case of badly prepared synthetic compound in which some phenol or para-salicylic acid is causing the damage to the patient. Some salicylic acid may undergo decomposition, total or partial, with liberation of phenol or compound of phenol, and in fact, some samples of salicylic acid smell of phenol. Sodium salicylate is the form in which the salicylates are usually administered, and it is well borne by most people. If given in solution with excessive alkali it is infinitely less irritant to the gastric membrane than when given in powder.

Salol, which is phenyl salicylate, also has a disadvantage of breaking up into salicylic acid and phenol in the intestine, and hence should not be given if the patient is suffering from kidney leisons. This often acts well, and usually in the amount given is non-toxic, but it cannot be pushed to as high doses nor does it seem to be so rapidly absorbed as sodium salicylate. It is less disturbing to the stomach, and some individuals whose gastric mucous membranes are unusually sensitive to sodium salicylate can tolerate salol. Salophen, which is the acetyl paramido phenol salicylate, had quite a vogue at one time, but seems to have fallen into disuse. Like salol, it has the phenol element in it, and like salol I have seen it rapidly reduce pain and fever in rheumatism when other forms of salicylate could not be tolerated.

Croftan recommends aspirin as the least irritating to the stomach, intestines and kidneys; he believes that this is the best form of salicylate, and declares that it possesses hardly any toxic symptoms. I have seen a few patients in whom aspirin seemed to be most irritant to the gastric mucous membranes, and produced the general toxic symptoms of the salicylates very rapidly in small doses. In my own experience it has not been as satisfactory for the reduction of fever and an improvement in the general condition of the patient as either sodium salicylate or oleum betulæ; in severe cases of rheumatism I have failed to get satisfactory results with it. This probably is due to the presence of the acetyl group, which causes this substance to be slowly broken down and thus probably slowly absorbed. There seems to be no question that to obtain rapidly beneficial results we must have a form of salicylate which is acceptable to most gastric mucous membranes, is quickly absorbed, and hence produces its effect quickly, and then is quickly excreted, that there may be no accumulation in the body.

Some years ago Kinnicutt recommended the oil of wintergreen, which is a natural methyl salicylate. This natural oil of gaultheria is no longer on the market, but the oleum betulæ or oil of sweet birch is, and it contains the same natural methyl salicylate. This form of salicylate in many ways fulfils the desired objects of which I have just spoken—the rapid absorption, the rapid excretion, and, to most people, a non-irritating effect on the gastric mucous membranes. In those patients with whom it disagrees, I have found it even when disturbing the stomach to cause less often the headache, the ringing in the ears, and the dizziness. It has been my experience that the majority of patients will respond more quickly and with less disturbance when the oil of birch is given them, than they will to synthetic sodium salicylate or the other forms of salicylates mentioned. Besides the advantages just mentioned, it has the further advantage of being a natural salicylate.

Dr. August Seibert of New York has recently recommended the hypodermic method of giving salicylates. The results reported are excellent, and this method may prove of advantage in those patients whose gastric membranes cannot retain the salicylates. The following procedure is recommended: In acute rheumatic infection of joints, heart, pericardium, pleura and central nervous system (chorea), 10 c.c. of a 20 per cent. sterilized solution of fresh sodium salicylate to 100 pounds of body weight are injected fifteen minutes after an appropriate cocain solution (gr. 1/8 to 30 drops of water) has been injected under the same spot. If the injections are made earlier than this, the solution will cause pain. This is repeated every twelve hours. In severe cases, with many localizations of the rheumatic process, the dose may be increased to 15 c.c. of the solution to 100 pounds of body weight.

It is considered essential to the success of this treatment that the above doses be used. Smaller doses will be without effect. The effect may be noticed within three hours after the first injection. Joint stiffness, pain, fever and pulse-rate diminish, and the general feeling of the patient improves. If the injections are continued regularly every twelve hours, the improvement also continues. If they are omitted for twenty-four hours in severe cases, the symptoms will grow worse, but in milder cases the improvement may continue. None of the injected patients presented symptoms of heart depression, ear buzzing, or profuse sweats. In the so-called chronic cases, 10 c.c. to 100 pounds of body weight of the following oily solutions are injected every twenty-four hours: acidi salicylici, 10 gm.; olei sesami, 80 gm.; alcohol, pure, 5 gm.; and gum camphor, 5 gm. The effect of the camphor on the heart is especially beneficial in pericarditis and endocarditis.[1]

Some months ago, a member of a well-known firm in New York suggested to me a form of salicylate which seemed to possess the various advantages of which I have just spoken, and to reduce to a minimum the irritating and toxic symptoms from its use. This salicylate is prepared as follows: oleum betulæ, the true oil of sweet birch, is taken and saponified either by superheated steam or caustic alkali, the resulting methyl alcohol driven off by heat, and the resulting salicylate decomposed by sulphuric acid and washed until free from sulphates; the salicylic acid is then purified by recrystallization. This salicylic acid is taken and mixed with a sufficient sodium bicarbonate in excess, and with a sugar binder is made into tablets, so that on solution each tablet will give five grains of sodium salicylate. This is freely soluble in water, with a pleasant acid taste, and with a free elimination of CO_2 gas. This seems to form a sodium salicylate in a nascent condition, for with the dry sodium bicarbonate and dry acid when the solution is made, they combine and fulfil the idea of nascent condition.

These tablets I have been using in a four-months' hospital service in Bellevue Hospital with very satisfactory results in severe cases of rheumatism. There has been a very noticeable lack of gastric irritation even when 20 grains were given every two hours, and when the ringing in the ears was produced and the dose diminished, this ringing quickly subsided. In some patients the fever fell rapidly before the pain ceased and the pain remained for a day or two after the fever struck normal, although very much ameliorated and so insufficient as not to cause much complaint from the patient. In most patients the pain and the fever disappeared coincidentally, while in others the pain rapidly improved in a few hours, and the fever disappeared a few hours later. In two patients with a marked galloping rhythm in the heart, and with increase in the cardiac murmurs, the belief was justified that there was a beginning myocardial inflammatory process. This cardiac condition subsided rapidly in three days, and the temperature went to normal and did not afterwards rise above, even to 99 or 100. Usually, as is well known, when the heart has become involved there is a rise to 99 or 100 for some time after the other symptoms have disappeared. In another patient with pericarditis, acute endocarditis and myocarditis and with a double rheumatic pleurisy, this form of sodium salicylate was the only form which had any beneficial influence. His pericarditis and pleurisy improved rapidly under these tablets. My supply gave out and again there was a recrudescence in the pleurisy and pericarditis. When I obtained more tablets, these processes rapidly improved under their administration. This improvement was so rapid and marked that it forced on me the impression that it was more than a coincidence.

---

[1] Seibert: Med. Rec., New York, March 11, 1911.

This form of salicylates seems to enable one to get a large amount of an active salicylate into the circulation at once, in the least toxic and most effective form of the natural salicylate. The process by which this form of salicylate is made is not an economical one, and it is unfortunately doubtful if it could ever be generally commercialized. It is here reported as an exceedingly active and useful form of salicylate, with a maximum of rapidity of absorption, effectiveness after absorption, and a minimum of toxic action.

In using salicylates in rheumatism, one is impressed by the rapidity with which they act when they act well and when the form of salicylate agrees with the patient, so much so that it is my belief that if within forty-eight hours a distinctly beneficial action is not obtained with the form of salicylate which is being used for that patient, we should use some other form. If sodium salicylate with large doses of sodium bicarbonate do not make a distinctly beneficial impression on the rheumatic process by the second day, it should be changed to the oleum betulæ, that is, the true oil of birch, and if the patient is resistant to that, it should be changed to salophen or some other form of salicylate.

36 East Thirty-First Street.

HERPES ZOSTER IN CONNECTION WITH KIDNEY LESIONS

M. KROTOSZYNER, M.D.
SAN FRANCISCO

Since Head's fundamental investigations on certain hyperalgetic cutaneous zones and their relation to affections of deep-seated visceral organs, it is generally accepted that pains located in these organs are transmitted to well-defined areas of the integument. The transmission of these pains is supposed to occur through fibers of the sympathetic nerve originating in the same cord-segments.

While these hyperesthetic zones, up to a short time ago, for want of better knowledge, were considered neurasthenic or hysterical stigmata, Head was the first to establish their anatomic importance as reflex phenomena. He proved conclusively that the location and extension of these hyperesthetic areas as dependent on pains of visceral organs coincided in many instances with the cutaneous eruptive zones of herpes zoster. In other words, by irritation of corresponding segmental fibers of the sympathetic nerve, paresthesias of pain are caused in certain zones of the periphery, which may be followed by the appearance of a typical herpes zoster.

The hyperalgetic peripheral zone of the kidney, according to Head, corresponds to that area of the integument which is innervated by the tenth and eleventh dorsal and the upper lumbar spinal nerves.[1]

During the last few months Bittorf, Kanera and Rosenberg,[2] each in brief succession, reported a case of herpes zoster of the tenth and eleventh dorsal nerves in connection with attacks of kidney colic caused by intermittent hydronephrosis, floating kidney and nephrolithiasis, respectively.

Since the literature does not contain other records of like or similar observations, the two following cases, which occurred in my urologic service of the German Hospital, are reported.

CASE 1.—*History.*—An attorney, aged 38 years, had suffered from frequent micturition and intermittent attacks of left-sided kidney colic several years prior to the appearance of a large fluctuating hydronephrotic sac on the same side, which about ten years ago was punctured and evacuated through a small lumbar incision. At the same time a small soft calculus, probably the cause of the ureteral obstruction and consecutive hydronephrosis, was removed from the pelvic portion of the left ureter. Gradually the same symptoms, pyuria pollakiuria and intermittent attacks of colic in the left lumbar region, set in again and became intensified. The patient's condition, of late, grew perceptibly worse, the main symptoms being strangury, frequent attacks of dyspepsia, headache and general malaise.

Examination.—General examination negative; kidneys not palpable; Wassermann negative. Urine cloudy, containing albumin and, microscopically, abundant pus. At two cystoscopic sittings the bladder presents the picture of a chronic cystitis; trigone congested; left ureteral orifice somewhat patulous; both ureters catheterized to pelvis; urine from right kidney is clear and normal, while that of the left side is cloudy and presents, chemically and microscopically, the same findings as the bladder urine. A marked deterioration of renal function (indigo carmin phloridzin, etc.) is found on the left side, while that of the right kidney appears normal. Blood cryoscopy shows 0.573. Radiographic plates negative for calculi-shadows. Renal secretion of left side shows pure culture of *B. coli*. On the basis of these findings, an advanced left-sided pyonephrosis is diagnosed and the patient prepared for nephrectomy on that side.

Two days before the date set for the operation, the patient complained of a slight chill and tenderness over his left thigh radiating toward the knee. On examination a herpetiform eruption was noted on the anterior surface of the left thigh in its center extending about 5 cm. in length and 2.5 cm. in width. Solitary blisters, also in center of anterior surface of thigh, were visible one 4 and one 5 cm. above and one about 10 cm. below the main focus. Temperature slightly elevated, reaching 100 F. but once.

Operation.—Under expectant treatment the zoster readily dried up, so that the contemplated operation could be performed nine days after the date first set. By lumbar incision a fluctuating sac of the size of a child's head was exposed; its enucleation was performed with great difficulty on account of many fibrous adhesions, which were particularly dense at the site of the old incision. The ureter was stitched to the lower angle of the wound which was closed by layers. The kidney tissue of the removed specimen, which represented a large sac, appeared to be reduced to a thin layer of fibrous tissue. Microscopic sections (Dr. Ophüls) show on inside of sac layer of vascular granulations and cicatricial tissue which is partly covered with stratified epithelium. In some sections the kidney tissue shows a diffuse fibrosis, dilatation of capsules of glomeruli, tubules wide, filled with desquamated epithelium. In other places all that is left is dense fibrous tissue. Patient made an uneventful recovery.

[2] Deutsch. med. Wchnschr., 1911, Nos. 7, 14 and 17.

Comment.—The cutaneous zone of herpes zoster in this case corresponds, according to Head, to the first and second lumbar (or ileo-inguinal, genitocrural and external cutaneous) nerves. The course and extension of the skin lesion comprises an area which is innervated by the crural branch of the genitocrural and the middle cutaneous nerves, which latter nerve has communicating fibers with the crural branch of the former. It is possible that the eruption of herpes was superinduced in this case by the passing of the ureter catheter to the left renal pelvis, as the patient, soon after each cystoscopic sitting, complained of colicky pains in the left lumbar region. In the three cases reported in the German literature, the herpetic eruptional zone was located on the back in or near the lumbar region, corresponding to the last two dorsal nerves, while the location of the zoster on the anterior surface of the thigh in my own observation suggests an irritation of the lower or lumbar portion of Head's spinal center for kidney affections.

Since writing the above I find an analogue to the location of the herpetic cutaneous zone in two cases of herpes zoster reported by Rosenbaum,[3] in connection with kidney affections. One of the observations concerns a girl of 11 years, who had to undergo nephrectomy on account of a left-sided kidney rupture. Eighteen days after the accident, a zoster appeared over the lumbar region as well as on the lateral and anterior surface of the thigh on the left side, an area which is innervated by the upper roots of the lumbar plexus.

Case 2.—*Past History.*—A farmer of 51 was admitted to the hospital in August, 1910, on account of intermittent attacks of right-sided colic radiating from the costal arch downward. The attacks had gradually increased in severity during the last year, occurred about once a month and were invariably connected with vomiting of bile. Nothing of pathologic note could be ascertained by the general examination and clinical observation. On account of the presence of microscopic pus in the urine, a right-sided renal lesion (probably nephrolithiasis) was suspected, a presumption which was not substantiated by either the cystoscopic or radiographic examinations. Both renal secretions were clear and microscopically and functionally normal. Sugar reaction, for instance, was strongly positive on both sides almost simultaneously, fifteen minutes after phloridzin injection. On these findings a right-sided renal lesion was ruled out and a previous gonorrheal infection, involving the prostate, was held responsible for the pus found in the urine. With no other evidence in favor of the probable existence of a cholelithiasis or, possibly, a chronic appendicitis than the symptoms present during the attacks, an exploratory laparotomy was performed at the patient's own request revealing all abdominal viscera normal, save an elongated and tortuous appendix which after its removal showed an obliteration of the lower half of its lumen. The patient's rapid recovery was, about two weeks after the operation, interrupted by a slight chill, rise of temperature and tenderness over the right chest and back, where an herpetic eruption appeared extending from the external margin of the manubrium sterni to the median line of the back. The zoster, for as such the cutaneous lesion was readily recognized, covered the sixth costal interspace extending to the tenth intervertebral space on the back, corresponding to the tenth dorsal nerve of the spine. The zoster gradually healed within two weeks and the patient returned to his home in the country in excellent condition. A few months later the same attacks of right-sided abdominal colic set in again with greater intensity and more frequently than before. The patient began to suffer from frequent and urgent micturition, independent of the attacks, and the urine which was repeatedly sent for examination was cloudy and contained pus in abundance. The pains during the attacks were now reported to radiate toward the bladder and scrotum. The patient reentered the hospital last May.

Examination.—Cystoscopy now showed the picture of a marked cystitis; right ureteral orifice pouting, emitting turbid fluid; the right renal secretion was cloudy and contained, microscopically, abundant pus and numerous blood-shades, while the urine obtained from the left kidney appeared macroscopically and microscopically normal. Functionally, the right kidney was found to be materially deteriorated as against its left mate, from which normal values were obtained. Blood cryoscopy showed 0.568, *x*-ray plates were negative for calculi shadows. Pyelography demonstrated the moderately enlarged and irregularly shaped right renal pelvis to be located unusually high between the ninth and eleventh costal interspaces. The injection of collargol solution required for pyelography caused, as the patient stated, the same pain as during the previous attacks of colic.

Operation.—Exposure of the right kidney was extremely difficult on account of its location high under the ribs and owing to many dense perinephritic adhesions. A severe hemorrhage occurred from an aberrant renal blood-vessel imbedded in adhesions and covering the ureter near the lower pole of the kidney. Finally, the organ was sufficiently freed to permit nephrotomy. The cut surfaces of the kidney presented many small cavities containing pus and sandy detritus; the renal pelvis and upper portion of the ureter were widened and filled with pus and fragments of gravel. The kidney was therefore removed, a small tear in the pleura was carefully repaired and the wound closed in the usual manner.

The patient rallied well from the operation and made an uneventful recovery. At the time of his discharge from the hospital he urinated about once every six hours; urine clear; its daily quantity about 1,800 c.c., microscopically normal. The patient's general condition was excellent.

Comment.—Although the location of colicky pains pointed in this case to a kidney lesion, an exact diagnosis could not be made for many months on account of the negative palpatory, cystoscopic and radiographic findings. The appearance of the zoster soon after the first operation was most decidedly superinduced by the bruising of intestinal loops and sympathetic fibers during the exploration of the abdominal cavity. The location of the zoster on the chest and back, somewhat above Head's renal zone and corresponding to the tenth dorsal nerve, finds its explanation in the unusually high position of the diseased kidney. The case proves the correctness of Head's teachings and clearly demonstrates the diagnostic aid which could have been derived, at the time, through the correct interpretation of the herpetic eruption on Head's cutaneous zone for kidney lesions.

CONCLUSIONS

A careful investigation of Head's hyperalgetic cutaneous zones should in future be made in all cases of abdominal colic of otherwise doubtful character.

2672 Pine Street.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

LANOLIN.—A non-proprietary name applied to Adeps Lanæ Hydrosus, U. S. P. For description see the Pharmacopeia or the Physician's Manual of the Pharmacopeia and National Formulary.

COLON BACILLUS VACCINE.

G. H. Sherman, Detroit.

Colon Bacillus Vaccines.—Marketed in two strengths: 1. Each Cc. contains about 40,000,000 killed bacilli. 2. Each Cc. contains about 100,000,000 killed bacilli.

GONOCOCCUS VACCINE.

G. H. Sherman, Detroit.

Gonococcus Vaccines.—Marketed in two strengths: 1. Each Cc. containing 20,000,000 killed bacteria. 2. Each Cc. containing 100,000,000 killed bacteria.

Gonococcus and Staphylococcus Albus Vaccine.—A mixed vaccine containing in each Cc. gonococcus 100,000,000 and staphylococcus albus 400,000,000.

PNEUMOCOCCUS VACCINE.

G. H. Sherman, Detroit.

P [illegible] in two forms: 1. Containing in e[illegible] ococci. 2. Containing in each Cc. [illegible]

Pneumococcus and Streptococcus Vaccine.—A mixed vaccine containing pneumococcus 30,000,000 and streptococcus 20,000,000.

STAPHYLOCOCCUS VACCINES.

G. H. Sherman, Detroit.

Staphylococcus Pyogenes Albus Vaccine.—Each Cc. contains about 300,000,000 staphylococcus pyogenes albus.

Staphylococcus Pyogenes Aureus Vaccine.—Each Cc. contains about 300,000,000 staphylococcus pyogenes aureus.

Staphylococcus Pyogenes Albus and Au[illegible] in four forms: 1. A mixed vaccine contai[illegible] coccus pyogenes albus and aureus each [illegible] vaccine containing in each Cc. staphylococcus pyogenes albus and aureus each 200,000,000. 3. A mixed vaccine containing in each Cc. staphylococcus pyogenes albus and aureus each 300,000,000. 4. A mixed vaccine containing in each Cc. staphylococcus pyogenes albus 400,000,000, and staphylococcus pyogenes aureus 200,000,000.

Staphylococcus Pyogenes Albus, Aureus and Citreus Vaccine.—A mixed vaccine containing in each Cc. Staphylococcus pyogenes albus, aureus and citreus each 100,000,000.

STREPTOCOCCUS VACCINE.

G. H. Sherman, Detroit.

Streptococcus Erysipelatis Vaccine.—Each Cc. contains about 20,000,000 killed streptococci erysipelatis.

Streptococcus Pyc[illegible] in two strengths: 1. Containing in ea[illegible] streptococci. 2. Containing in each Cc. [illegible] cci.

Streptococcus Pyogenes and Micrococcus Catarrhalis Vaccine.—A mixed vaccine containing in each Cc. streptococcus pyogenes 30,000,000 and micrococcus catarrhalis 100,000,000.

Streptococcus Pyogenes, Staphylococcus Pyogenes Aureus and Albus Vaccine.—A mixed vaccine containing in each Cc. streptococcus pyogenes 30,000,000 and staphylococcus pyogenes aureus and albus each 100,000,000.

Streptococcus Pyogenes and Colon Bacillus Vaccine.—A mixed vaccine containing in each Cc. streptococcus pyogenes 30,000,000 and colon bacillus 40,000,000.

Staphylococcus Pyogenes, Pneumococcus and Staphylococcus Pyogenes Aureus Vaccine.—A mixe[illegible] h Cc. streptococcus pyogenes 30,000,[illegible] and staphylococcus pyogenes aureus

Streptococcus Pyogenes, Staphylococcus Pyogenes Aureus and Albus Vaccine.—A mixed vaccine containing in each Cc. streptococcus pyogenes 60,000,000, staphylococcus pyogenes albus and aureus each 200,000,000.

TYPHOID BACILLUS VACCINE.

G. H. Sherman, Detroit.

Typhoid Bacillus Vaccine.—Marketed in three forms: 1. Each Cc. contains about 50,000,000 killed typhoid bacilli. 2. Each Cc. contains about 500,000,000 killed typhoid bacilli. 3. Each Cc. contains about 1,000,000,000 killed typhoid bacilli.

Therapeutics

TUBERCULOUS MENINGITIS

Few diseases are more discouraging to the practitioner, or more disastrous in their results than tuberculous meningitis. Except during the occurrence of epidemics of cerebrospinal meningitis, tuberculous meningitis is estimated by Holt to cause 75 per cent. of the deaths from acute meningitis in children. While epidemic meningitis occurs most frequently between the ages of 2 and 15 years and is also frequent in children under 2 years of age, a very large proportion of the cases of tuberculous meningitis occurs in children under 1 year of age, and particularly between the ages of 9 and 12 months. Some observers think these cases more frequent in April, May and June than in other parts of the year, and conclude that this is due to the general prevalence of respiratory diseases during the late winter and early spring months.

This disease is now definitely recognized as being caused by the tubercle bacillus. It has been generally considered that heredity has a very considerable influence in the etiology of the disease, but the tendency among modern observers is to conclude that what has been heretofore classed as hereditary influence is really exposure of the child to direct contagion from persons suffering from pulmonary tuberculosis. Perhaps children between 9 and 12 months of age are more exposed to this sort of contagion than children of other ages, and also perhaps this sort of contagion is especially operative during the spring months.

It is probable that the contagion is taken into the body through the respiratory organs, and is transmitted to the brain through the circulation. The old idea that the contagious element was transmitted to the brain through the cribriform plate of the ethmoid bone seems to be losing favor.

On post-mortem examination of children who die with tuberculous meningitis the most extensive pathologic changes are found at the base of the brain, and it has been said that cases in which the pathologic lesions are confined to the convexity of the brain are unknown. The lesions affecting the brain may extend to the spinal cord and to the ventricles of the brain. These pathologic changes often appear to be slight compared with the gravity of the symptoms which have been observed during life.

Some have supposed that the disease is more likely to affect delicate and ill-nourished children, but careful observation seems to have shown that this is wrong, and that well-nourished and healthy children are apparently as likely to be affected by the disease as those who are debilitated and ill-nourished.

The disease often comes on insidiously. A slight change in disposition may be the first symptom noticed. There may be irritability, or an indisposition to take notice of and be interested in things that are going on. One of the earliest prominent symptoms is headache. This may be exceedingly severe, and is likely to be attributed to some other cause, as stomach disturbance, or constipation. Headache is not so common in children as in adults, and a continuous headache, if the child is old enough to complain of it, should arouse suspicion of the presence of some intracranial trouble. Vomiting is a common early symptom. It may be of the projectile character, and unaccompanied by nausea. Fever is an early symptom. It may not be of high grade at first, but usually after several days attains a height of from

103 to 105 degrees. Occasionally the earliest symptom to arouse alarm is a severe convulsive attack. This may be followed by other convulsions at longer or shorter intervals.

After the disease has lasted a variable number of days, usually from five to ten, the patient begins to become stupid, and finally becomes entirely unconscious.

Twitchings of the muscles of the arms and legs are common, and the muscles moving the eye-ball may also be affected by these localized convulsive movements. The muscles in the back of the neck and along the spine usually become more or less rigid early in the disease, so that lifting the head or moving the body causes pain. The Kernig sign is usually present. This can be determined by flexing the thigh on the body and then extending the leg on the thigh. If there is irritation of the nervous system from meningitis, this movement will be accompanied by pain and an increasing concavity of the dorsolumbar spine.

The pupils at first may be contracted, but usually later are dilated. The fontanels may be distended.

Death may occur in five or six days, or the disease may be protracted for from two and one-half to three weeks. Rarely the patient lives four or five weeks. Most cases terminate fatally; only exceptional cases of recovery have been reported.

It would seem that the diagnosis of the disease is commonly attended with some difficulty. Certainly a large proportion of mistakes are reported by hospital physicians who see cases after they have been seen by outside practitioners. At the present time it would seem that no one is justified in treating a patient in whom the possibility of the presence of this disease must be taken into account, without performing a lumbar puncture and having the spinal fluid examined microscopically. Since lumbar puncture was introduced by Quincke, in 1891, it has gradually grown in importance as an aid to diagnosis. Like the results of other methods of diagnosis, the results of this method are not invariably infallible, but the results are definite in so large a proportion of cases that its employment should never be neglected. As a rule the tubercle bacillus is found in the spinal fluid obtained by lumbar puncture. Some writers state that this is the fact in 90 per cent. of cases.

Examination of the cells contained in the spinal fluid should also be made. It has been supposed by some investigators that the character of these cells indicated the character of the meningeal inflammation; that in epidemic meningitis polynuclear cells were found in the exudate, while in tuberculous meningitis the mononuclear cells or lymphocytes were present in greater proportion. While perhaps these conditions exist in the majority of cases, it is now believed that the lymphocytes characterize diseases of long standing, and that they may be found in cases of epidemic meningitis which have been protracted.

The other symptoms which are to be taken into consideration in making a diagnosis are the headache, the retraction of the head, the vomiting, and the gradually increasing stupor. The diseases which must be borne in mind and which should not be mistaken for tuberculous meningitis are epidemic meningitis, meningitis due to other forms of infection, malarial infection, influenzal gastro-intestinal disorders, various toxic conditions, and middle-ear or mastoid inflammation.

Besides the lumbar puncture, another diagnostic aid which is of considerable value in this disease is the von Pirquet reaction. The cutaneous reactions from this test are not objectionable, and the test is not a difficult one to employ. Lucas, of Boston, found that of thirty cases of tuberculous meningitis, twenty gave positive reactions. This indicates that the method has considerable value, but cannot be absolutely relied on in every case.

The treatment of this disease cannot be undertaken with any expectation of a cure. The prognosis is so very grave, and recoveries are so rare, when the disease is definitely determined to be tuberculous in character, that much cannot be expected, and but little hope can be held out to the parents, from any treatment.

The treatment should be commenced with a thorough evacuation of the bowels with a large dose of calomel. To a child a year old as much as a grain may be given at one dose. It is better to give this amount in a single dose than to give it in divided doses.

External applications are held in considerable repute by most practitioners. If it can be determined early in the disease that there is an inflammation at the base of the brain, depletion of the vascular system should be employed. This may be accomplished by the application of one or two leeches over the mastoid process. Cold, by means of ice-bags, should be applied intermittently to the head, and ice-bags may be applied over the spine; or, counter-irritation may be used by means of a mild mustard paste, applied over the whole length of the spine or over the neck and back of the head.

Other internal medication which may be administered with a view of palliating the uncomfortable symptoms, include opium, which may be administered if the child seems to suffer acute pain in the head, as evidenced by constant severe crying, and insomnia.

If there is restlessness and muscular twitching, and convulsions, the bromid of sodium should be given, in a dose of 0.30 gm. (5 grains), to a child 1 year old, repeated in four hours, if needed.

After the first week the iodid of sodium may be given with the hope (generally a vain one) of removing the products of inflammation at the base of the brain. A twentieth of a gram (about 1 grain) may be given three times a day to a child one year old. Large doses are of no value, and will do harm.

Liquid nourishment should be given in the form of milk, either plain or diluted with lime water, or peptonized. It should be given at regular intervals, both to relieve the thirst and to maintain the nutrition.

The internal use of remedies intended to destroy the bacillus has not found many advocates. If one were inclined to feel that the administration of such remedies increases the hope of recovery, one might administer creosote, in doses of 1/4 drop, repeated at intervals of three hours.

In view of the comparatively recent observation that hexamethylenamin has been found in the cerebrospinal fluid a short time after it has been taken by the mouth, it might seem desirable to administer this drug in tuberculous meningitis, but it is not reasonable to expect that such favorable results will follow its use in this disease as have been reported from its use in epidemic cerebrospinal meningitis.

The preventive or prophylactic treatment demands that all children should be absolutely separated from every individual suffering from pulmonary tuberculosis. In this way only can one feel confident that the disease may be avoided. Furthermore, as the tubercle bacilli are believed to be more or less present everywhere where human beings are found, by systematic cleansing of the mouth and throat, one may hope to avoid contamination with the bacilli.

SATURDAY, SEPTEMBER 9, 1911

VIRCHOW'S GENEROSITY

It is well known that in the last years of his life Virchow was very much of a reactionary. He who, in his ardent youth, had been a fiery champion of democracy and a passionate advocate of the improvement of medicine and public hygiene in the broadest sense, in later years, as our German confrères have been not slow to remind us, became a typical caviler and a sort of cool devil's advocate in regard to many things of the utmost importance to the great preventive movement of our time.

There is no need to censure Virchow for his lukewarm attitude toward Darwinism. He was an expert anthropologist and craniologist and his views on natural selection and the descent of man were entirely his own affair. They did not hinder the growth of the doctrine of evolution. But it cannot be denied that Virchow's relation to the work of Koch, Behring, Loeffler and the other leading expositors of the bacterial theory of infection was one of smug civility and ill-concealed indifference, if not of positive *nil admirari*. The reason is not far to seek. Like all old men he was an inevitable conservative, and it did seem, at first blush, as if the modern theory of the blood-serum as the battle-ground of the infectious processes, in all appearance a revival of the humoral pathology of Hippocrates, would be likely to displace the "solidist" conceptions (*omnis cellula e cellula*) advanced by Virchow himself. It was natural enough that the old veteran should decline to wear "the foolish face of praise," since he could not foresee that Ehrlich would come to the rescue of his cellular pathology by showing that the seat of war is, after all, in certain specialized atom-groups belonging to the peripheral molecules of the cells themselves. Neither should we resent Virchow's disapprobation of the course of the United States in the Philippines. If, as President Andrew D. White once related,[1] even Mommsen the historian could not understand how we were driven to take possession of those islands, it is hardly likely that Virchow could.

A man has a right to be judged by the best that is in him, and we may contrast the ultra-conservative Virchow of the declining years, not so much with the "heaven-storming" youth who pitched into Bismarck about the typhus fevers in Silesia, as with the mature man of middle life who gave us those fine, catholic appreciations of Harvey (his favorite historical figure), Bacon, Morgagni, Glisson, Schönlein, Schliemann of the Trojan excavations and Pope Innocent III, the pioneer of the great hospital movement in the Middle Ages. We have spoken of his attitude toward this country during the Spanish-American war. It did not ruffle America in the least. Why? Because American physicians can never forget Virchow's classical tribute of praise to the work of the Medical Corps of the United States Army during the Civil War,[2] especially of the "critical, truly scientific spirit, open-mindedness, sane and practical common sense which gradually penetrated all circles of the American army administration, and with the wonderful cooperation of an entire nation, reach the high-water mark of humanitarian achievement in any great war on record." The publications of the United States Army Medical Department of this period made, he asserts, "a new era in the history of military medicine."

Perhaps, however, the most striking example of Virchow's enthusiasm and generosity of spirit is his noble tribute to Pasteur. When the great chemist died he was by no means a popular figure in Germany owing to the fact that, from a natural soreness over the reverses of his native country in the Franco-Prussian War, he had declined the degree conferred on him by the University of Bonn and other distinctions offered by the German government. In consequence he was frequently caricatured and belittled in certain quarters, and even Koch was, at first, anything but well-disposed toward his work. When Pasteur passed away in 1895, it devolved on Virchow, as president of the Berlin Medical Society, to pay the usual memorial tribute to the illustrious dead.[3] He began by pointing out that the newspapers (as usual) misrepresented Pasteur's position in science by hailing him as the discoverer of this or that bacillus. Pasteur's claims (and here Virchow's words begin to turn to flame) were of an entirely different order. His position in science is immortal, first, by his conquest of the doctrine of spontaneous generation; again, because he was the first to handle the bacterial theory of infection in "the grand style," and thence to attempt a working theory of immunity and a practical enlargement of Jenner's original scheme of preventive inoculation. It is certain, says Virchow, that the whole modern tendency of such inoculations owes its inception to Pasteur, and no physician, only a chemist, could have hit on his peculiar modes of experimentation. After enlarging on this theme, Virchow winds up in a tone of reasonable protest against the German misunderstanding of Pasteur's true position as a patriot. He reminds his fellow countrymen that Pasteur laid the foundations of his scientific work as a teacher in Strasburg, now a German city; that it was in Strasburg that he found his wife, and that he must have loved this place with his whole heart. That the loss of this place to his country should have affected him deeply, we who love our own country, said Virchow, should not hold up as a fault against him. When we consider how little enthusiasm Virchow had for the modern theory of infection and its consequences, this defense of Pasteur seems one of the finest actions of his life.

THE CHARGE AGAINST DR. WILEY

When the charge against Dr. Wiley was first made public even his friends supposed that it could be at least sustained on a technicality. The investigation has brought out the fact that Dr. Wiley was not guilty of even the trivial technical violation that was claimed. The charge was that he had made a secret agreement with Dr. Rusby concerning the rate of compensation the latter was to get, based wholly on a letter which Dr. Wiley was alleged to have received from Dr. Rusby. This letter is reproduced in full elsewhere.[1]

It will be noticed that in this letter the agreement spoken of by Dr. Rusby was to be subject to the approval of the Department of Agriculture, or as he put it, valid "if approved by the department." This part of the letter was suppressed by the Committee on Personnel in submitting its charges against Dr. Wiley to Secretary Wilson. Nor was this all; it was proved that this letter had neither been received by Dr. Wiley nor sent to him. Dr. Rusby had written the letter, it is true, but it had never been sent. A carbon copy of the letter, however, found its way into Dr. Rusby's files and, with a mass of other material was sent by him to the Committee on Personnel when he was requested to furnish a copy of all his official correspondence. It was further brought out that the Committee on Personnel had the means of knowing that this letter had not been received by Dr. Wiley because he had sent a complete list of all the letters that he had received and had also stated that no personal letters had ever passed between him and Dr. Rusby on this subject.

To sum up, the case amounts to this: The charge against Dr. Wiley was that he had entered into a secret agreement with Dr. Rusby by which the latter was "to be paid an illegal rate, differing from the rate specified in the appointment." The facts were: No such contract was ever made; the letter on which the committee based its charge that such a contract had been made had never either been received by Dr. Wiley or sent by Dr. Rusby. While a letter on the subject had actually been written by Dr. Rusby, even had it been sent, it was perfectly plain that there was no idea of any "secret agreement," as it was specifically stated that the rate of compensation would be agreed to by Dr. Rusby only "if approved by the department." In spite of all this, the enemies of the chief of the Bureau of Chemistry used this letter which they had means of knowing had not been received by Dr. Wiley and, not content with that, they suppressed the very part of the letter which, even had it been sent, would have made it impossible for them to bring the charge against him of having entered into a "secret agreement" for the purpose of evading the law.

The enemies of the pure food law at Washington must be in desperate straits when they find it necessary to attempt to oust honest and efficient public servants by means of trumped-up charges of a trivial and technical nature based on manufactured evidence and on garbled and suppressed facts. Dr. Wiley and his associates have come out of the present investigation completely vindicated and more firmly entrenched than ever in the hearts of the American people.

While the investigating committee has adjourned temporarily and will not submit its findings for some weeks, the public, through the press, has already delivered judgment. Dr. Wiley is not only innocent of even the trivial technicality brought against him, but he has been shown to be the victim of as unprincipled a conspiracy as was ever manufactured against a competent and public-spirited official. Many interesting details have been brought out in this investigation that the public and the medical profession ought to know. Some of these appear elsewhere[1] in this issue; others will follow.

THE VENDER OF INTELLECTUAL NOSTRUMS

It was a notable warning which President Butler recently gave the graduating class of Columbia University, against the nostrum-venders, political, literary and religious—and he might well have added, the medical—all of whom now so dreadfully infest our American civilization. These, he well observed, are the men of "new ideas" (such ideas as Plato discarded many centuries ago as perverse); the men (and women) who preach "new thought" without ever having learned to think; the multitudinous advocates of change for the sake of change; of reforms springing from no need and growing out of no experience; the shallow, unqualified, half-baked horde who are letting loose on the land a torrent of talk, to the degree that "the educated man or woman of to-day has literally to struggle against being swept into the current of irrationalism."

Knowledge has come on our people in veritably cyclonic measure, while wisdom has emulated the snail in its progress. "The marvelous last half-century of science," continued President Butler, "has made absolutely no impression on the thinking habit. Science has destroyed many prepossessions and not a few beliefs; but it has not yet taught mankind to think. Our age is far less reflective than was the eighteenth or the first half of the nineteenth century; our people are now ever busy hunting for something new."

---

[1] Propaganda for Reform department, this issue, page 913.

"The present age is certainly that of the crowd and the demagogue," continued the president of Columbia. The crowd, with its well-marked mental and moral peculiarities, is everywhere in evidence; and demagogues of all kinds din its ears with hungry cries. The art of demagoguery is easy, and it is quickly learned; and the rewards of its successful practice "have strange fascination for minds and characters that we would like to think in all respects worthy."

Thus has President Butler pilloried the literary, the political and the religious demagogue. We should for ourselves have prefixed the qualification "pseudo" to each of these adjectives. Nor are Butler's observations any the less applicable to the pseudomedical demagogue, and the amazing impression he makes on the crowd. Indeed, the offices of religious and medical nostrum-vender are quite generally combined in the one engaging personality. The "new-thoughter," for example, while piloting you skyward, will at the same time attend to your physical well-being—for a consideration. There are in point of fact, literally hundreds of cults—essentially psychopathic epidemics—in the United States that are thus dominated. It is unpleasant indeed to observe in them how often the abnormal, the insane even, have exerted, and now exert, a noxious influence on people who are, to begin with, evenly enough balanced. The pseudoreligious movements (which quite invariably undertake to heal also the body) have in common certain well-defined earmarks. Each despises and decries all the rest: With us, assures one leader, you shall find peace here and hereafter, with the cure of all your ailments; but as you hope to escape eternal perdition, have nothing to do with that shop across the way! Some of these cults are offshoots from others, enterprises originated and conducted by malcontent demagogues who have not had a fair share of the spoils from their erstwhile leaders. The demagogue in charge of each cult—its nostrum-vender-in-chief—insists incessantly and blatantly that its tenets are the only true ones; and its devotees will as insistently, and much more blindly, back him up. There never, by any chance, was a true system other than the particular one under consideration. Any given demagogue can never, by any accident, make a statement that is not consonant with the plain, unvarnished truth. Each demagogue strives, with most consummate assurance, to outdo all others in extravagant claims (such as are impossible in nature) to have achieved marvelous and miraculous results, especially in the cure of disease. But no statement any leader ever made is more marvelous than the gullibility with which the devotee has accepted it. "Far-fetched analogy, baseless assertion, the uncritical assimilation of popular superstitions, a great deal of prophecy after the event, much fanciful elaboration of detail, ringing the variations on a sufficiently complex and non-demonstrable proposition, cultivating a convenient vagueness of expression, together with an apologetic skill in providing for and explaining exceptions, the courage to ignore failure, the shrewdness to profit by coincidences and half-assimilated smatterings of science, and, with all, an insensibility to the moral and intellectual demands of the logical decalogue"—such, observes Jastrow, are the elements on which the medicoreligious nostrum-vender rides to most meretricious success.

Current Comment

LANOLIN NOT PROPRIETARY

As long ago as 1902, a court decision of great importance to physicians was rendered, which, curiously enough, seems to have escaped the notice of the medical profession. At that time, the court held that the word "lanolin," first applied to wool fat by the original patentees, was a general designation for that substance, and that this word became a non-proprietary name when the patent on the product expired. Although it is nine years since this decision was rendered, many physicians still avoid using the term "lanolin" and use the somewhat cumbrous title of the Pharmacopeia. To help remove the misapprehension that exists regarding the use of this word, the Council on Pharmacy and Chemistry has decided to list lanolin as a synonym for hydrous wool fat (adeps lanæ hydrosus) in New and Nonofficial Remedies.[1] Physicians can therefore use the shorter term, as it is now public property.

INFANTS' MILK DEPOTS AND THE RESULTS OF THEIR OPERATION

Following a plan carried out in 1908 and 1909, Dr. J. W. Kerr[2] of the Public Health and Marine-Hospital Service, assisted by Drs. Henry L. Coit and Roland G. Freeman (the three constituting a committee of the American Association of Medical Milk Commissions), has compiled data concerning the operation of infants' milk depots in the United States in 1910. The results, while interesting, are not conclusive as to the exact value of these depots, the principal and important reason being the lack of accurate vital statistics in many of the states and cities where this work is carried on. Data were received from forty-three institutions located in thirty cities, and while the general object of all the depots is the protection of infant life, on account of the lack of uniformity of specific objects and of methods, and incompleteness of statistics, the results in the different cities are not comparable in such a way as to bring out the true value of this work. There was difficulty in determining in every instance whether it is the endeavor of the institution to accomplish good by meeting the purely hygienic needs of infants or simply to relieve the distress brought about by poverty. The data compiled, however, cover, among other things, the following points: object of institution; method of operation and manner of maintenance; instruction to mothers in infant hygiene, given by physicians or nurses, in the homes or in central consultations; distribution of the milk by agencies, free or otherwise; proportions of infants who were ill and well, number fed, average age, quality and preparation of milk, modifications, etc., and, chief among the objects of inquiry, the mortality-rate of infants under 1 year of age, and among children fed on dispensary milk one month or over during the year. The tabulations of this report show that the mortality-rate for infants under 1 year varied from 12 to 30 per cent., and in children fed on dispensary milk for one month or over during the year, from no deaths to 20 per cent. These figures may or may not prove much, but the information obtained is of interest and emphasizes the importance and necessity of uniformity of methods in conducting these institutions, and the supreme importance of accurate and uniform reports on births and deaths. On this latter point the report says: "The correct infant mortality-rate is the ratio of deaths of infants under 1 year of age to the number of children born alive during the year. In the absence of registration of births in many cities, therefore, no such rate can be determined, and since registration of births in the great majority of cities is very incomplete, any ratio based on the returns would be misleading. The data presented indicate how desirable it would be to know the correct infant mortality-rate, and emphasize in some measure the importance of the accurate registration of both births and deaths." It might also be added that until these two objects are attained and the various agencies for infant welfare are better coordinated, much effort and expenditure in this direction will be wasted.

THE "CASE" OF THE PHYSICIAN

The physician and the lawyer both deal with "cases"; but while the latter has not learned to call his client a "case" (except jocularly), the former often seriously applies to his patient the word which properly signifies the given instance of disease or the given group of facts constituting the condition. The misuse of the term is an unfortunate one, not so much for the language as for the profession. The language has assimilated without disaster many more violent metonymies; but the habit of mind to which this particular figure of speech bears witness is one which works against mutual sympathy and confidence between the physician and the patient and even against real professional usefulness. The surgeon who really thinks of his patient as a "case" is the one who is inclined to be satisfied with a mere operative recovery; the physician with the same tendency of mind is likewise inclined to be satisfied if he has demonstrated his own skill, even if he has not penetrated far enough into his patient's characteristics and circumstances to know the ultimate causes of the disease and the probability of its recurrence. Whatever the scientific attainments of a physician, there is nothing which more surely alienates the public from him than this tendency to regard his patient as a mere living illustration or embodiment of disease or injury. The physician himself may be the last to become aware of this feeling, for it is not often so adequately voiced as it was by one mother, who, exasperated by the constant reiteration of "the case," exclaimed: "Dr. ——, I don't want to hear another word about the 'case.' This isn't a case; this is my baby." We suggest once more[1] that it is well to beware of confusing the "case" and the patient.

Medical News

ARIZONA

Personal.—Dr. Henri Ap John, Yuma, physician in charge of the Yuma reclamation project and in charge of the reclamation service hospital, has broken down from overwork, and is taking a few weeks' rest in southern California.——Dr. George F. Manning, Flagstaff, while stepping off a train, August 4, turned his foot, causing a sprain of the ankle.——Dr. Charles L. Edmundson, formerly mayor of Bisbee, has retired from practice and moved to Los Angeles, Cal.——Dr. Carl Lund, Douglas, has resigned from the medical staff of the Copper Queen and will practice in Oklahoma City.

CALIFORNIA

Laboratory for Hospital.—Mrs. Harriman, widow of the late E. H. Harriman, has given $50,000 for the establishing of a bacteriologic and pathologic laboratory to be attached to the present Southern Pacific General Hospital, San Francisco. It is to be known as the Harriman Memorial Laboratory.

Eradication of Squirrels.—A meeting was held in Modesto, August 26, at which the farmers were urged to help along the eradication of squirrels by establishing local poison squads. The purpose of establishing these squads is to prevent the spread of the squirrel-infested area into the foothills by clearing of squirrels a territorial belt in advance of the present area which is known as the suspected infected area, thereby making an additional barrier.

DISTRICT OF COLUMBIA

Personal.—Dr. Isadore Burman has sailed for Europe.——Dr. William F. R. Philips left August 22 to assume the professorship of anatomy in the medical department of the University of Alabama, Mobile.

Veiled Prophets' Committee.—The following is the medical committee announced for the Veiled Prophets' reception, September 25: Dr. Floyd V. Brooks, chairman; Dr. Lewis A. Walker, vice-chairman; Drs. Wade H. Atkinson, George K. Baler, Grafton D. P. Bailey, William H. Brandenburg, Clarence R. Dufour, Leon L. Friedrich, Frank E. Gibson, Edward M. Hasbrouck, Joseph Ernest Mitchell, William O. Owen, Ralph A. Quick, Edward G. Seibert, Lewis H. Taylor, Clarence A. Weaver and Frederick Yates.

GEORGIA

Personal.—Dr. J. Calvin Weaver, Atlanta, has been appointed surgeon of the Federal Prison, Atlanta, vice Dr. Alfred L. Fowler, resigned.——Dr. R. C. Orr, Athens, has been appointed a jury commissioner for Clarke County.

District Association Meeting.—The fifth annual meeting of the Eighth District Medical Association of Georgia and the Wilts County Medical Society was held in Washington, August 16, under the presidency of Dr. Richard J. Robins, Siloam. The following officers were elected: President, Dr. Thomas J. Wills, Washington; vice-president Dr. L. E. Roper, Comer, and secretary-treasurer, Dr. Daniel H. DuPree, Athens.

Work Done at Mount Alto.—The annual report of the State Tuberculosis Sanatorium, Alto, states that 180 patients were cared for during the year with 60 in residence, at its close. One of the main features of the institution is educational and the prevention of the disease is the point which the authorities desire to attain. An appropriation of $50,000 was passed by the House of Representatives, $25,000 of which is available next year and $25,000 in 1913. This money will be used for new buildings and sleeping quarters.

---

[1] See Bad English, Queries and Minor Notes, THE JOURNAL A. M. A., Dec. 22, 1906, p. 2108.

ILLINOIS

Hospital Attendants Suspended.—Plans of seven attendants of the Elgin State Hospital, to strike, August 29, because they were not allowed one day off each week, were frustrated by their prompt suspension from the state service.

Personal.—Dr. George S. Rainey, Salem, was elected surgeon at the twenty-ninth annual Illinois Soldiers' and Sailors' Reunion held in Duquoin, August 26.——Dr. Isaac F. Freemmel of the staff of the Elgin State Hospital has been temporarily transferred to the staff of the Illinois Hospital for the Feeble Minded, Lincoln.

Fire at Cook County Institutions.—A fire which occurred in the vacant west wing of the Cook County Institutions, Dunning, August 27, necessitated the removal of about two hundred patients from the Cook County Insane Hospital. They were removed without casualty under the care of Drs. Carl F. W. Eberlein, chief of the medical staff, J. A. Smith and Robert H. Rea. The fire caused a loss of $5,000. The medical staff and nurses were commended by the president of the county board for their excellent work in removing patients from the building during the fire.

Chicago

Theft of Medical Books.—Joseph Suffrin, who is said to have started a preparatory medical school with the books of reference stolen by him from the John Crerar Library; was sentenced to six months' imprisonment in the Bridewell, August 29.

Home from Europe.—Dr. and Mrs. Nathan S. Davis and daughter, and Dr. and Mrs. Edward L. Moorhead and son, and Dr. and Mrs. Edwin B. Tuteur and daughter, Dr. William H. Falker, Dr. and Mrs. Clarendon Rutherford, Dr. William C. Wermuth and Dr. Robert Von der Heydt have returned from Europe.

Fire in Hospital.—Fire on the fifth floor of St. Bernard's Hospital, August 25, caused considerable excitement but was not attended by any casualty to patients.——Fire in a building on the opposite side of the street caused a panic in the Practitioners' Hospital, August 30, which was stopped only by strenuous and cool-headed work on the part of the nurses.

Home for Consumptives.—The Jewish Consumptive Relief Society has purchased a tract of land bounded by Belmont, North Fortieth and North Fifty-First Avenues and School Street, on which an institution for the care of indigent consumptives will be started. It is planned to erect first an administration building to cost about $15,000 and several shacks at a cost of $2,000 to $3,000 each.

IOWA

Personal.—Dr. Edward S. Bowman, Davenport, recently underwent operation.——Dr. Joseph C. Collester was seriously injured in a collision between his automobile and a freight train near his home in Spencer, recently.——Dr. Gilbert Baldwin, Ruthven, was struck by an automobile recently and sustained painful injuries.——Dr. David E. Beardsley has been appointed a member of the staff of St. Luke's Hospital, Cedar Rapids, vice Dr. Walter S. King, deceased.

KANSAS

Personal.—Dr. Oliver J. Taylor, Wichita, is reported to be ill at his home.——Dr. J. R. Perdom, Wetmore, has been appointed a member of the advisory commission of the State Sanatorium for the treatment of tuberculosis.——Dr. James Stewart has been appointed city physician of Topeka, vice Dr. Henry B. Hogeboom, resigned.——Dr. Charles H. Ewing, Larned, has been appointed head physician for the Modern Woodmen of America for Kansas.

KENTUCKY

Gift to Kentucky Tuberculosis Association.—The Kentucky association for the cure and prevention of tuberculosis has received a gift of $500 from Mr. T. Coleman DuPont of Wilmington, Del.

Hospital Patients Moved.—The staff and nurses of the Louisville City Hospital safely removed 136 patients for six squares into temporary quarters to be occupied during the erection of a new hospital building on the site of the old.

Personal.—The recent quarterly meeting of the Kentucky Midland Medical Association, held in Louisville, closed with an elaborate banquet given by Dr. Louis Frank in honor of Dr. Urbane V. Williams, Frankfort, first president and oldest member of the association.——The bungalow of Dr. Edward R. Palmer, Louisville, at Harrods Creek, was destroyed by fire August 10, with a loss of several thousand dollars.

LOUISIANA

Benefit for Charity Hospital.—Plans for a mammoth benefit for the Charity Hospital, New Orleans, are in progress. The object of the benefit is the collection of funds for the erection of an isolation building for contagious diseases. The hospital will commemorate its centennial of state ownership in October.

Gifts to Presbyterian Hospital.—At a meeting of the board of managers of the Presbyterian Hospital, New Orleans, August 16, the receipt of a check for $20,000 from the estate of the late W. R. McKowen, Jackson, was announced. It was decided by the board to establish a McKowen Memorial Charity ward in the institution.——A complete *x*-ray department under a skilled radiologist is to be put in this month.

Personal.—Dr. Edward L. McGehee, Sr., has been elected president and Dr. John L. Robinson vice-president of the board of health of Hammond.——Dr. Charles Chassaignac has been made chairman of the executive committee to make up plans and carry forward the work of cleaning and sanitation in New Orleans in cooperation with the city and health authorities.——Dr. Creighton Wellman has been made professor of hygiene and preventive medicine in Tulane University.

MARYLAND

Baltimore

New House Staff.—The following constitutes the new staff of house officers of Johns Hopkins Hospital: medicine, Drs. Arthur E. Bloomfield, Ernest G. Grey, Helen W. Smith and Julian M. Wolfsohn; gynecology, Drs. Veader N. Leonard and Walter G. Sexton; surgery, Drs. Barney Brooks, Hans Lisser, John A. C. Coston and William A. Fronty, and obstetrics, Dr. Arthur S. Rosenfeld.

Personal.—Dr. William H. Welch returned September 1 after an absence of eleven weeks spent in traveling through Alaska and Canada.——Dr. William B. Treat was operated on recently for appendicitis.——Drs. Henry O. and A. J. Neilson Reik have started for Europe.——Dr. E. Longsdorf has been appointed physician to the Isthmian Canal Commission with station at Panama.——Dr. Howard A. Kelly was operated on at Rochester, Minn., August 31, for adhesions from old gall-bladder inflammation.——Dr. G. Halsted Boyland has returned from Europe.——Dr. Arminius C. Pole was stunned by lightning which wrecked the upper floor of his house during a severe storm, August 28.

MASSACHUSETTS

Bequests.—By the will of the late Miss Cornelia Francis Forbes, Westwood, $1,200 is bequeathed to the Vincent Memorial Hospital, Boston, and $300 to the Convalescents' Home, Milton.

Personal.—Dr. Edwin M. Murphy, Lowell, has returned from Europe.——Dr. Paul Carson head of the division of school hygiene of the health department of Boston, has resigned and will locate in Michigan.——Dr. Patrick J. Hughes has been appointed a member of the board of health of Lawrence, vice Dr. John H. Tobin, resigned.

NEW YORK

New York City

Hospitals for the City.—The city has filed plans for two four-story concrete hospital buildings on North Brother Island. The estimated cost of these buildings is $100,000.

Personal.—Dr. Fred H. Albee has been appointed professor of orthopedic surgery at Vermont Medical College.——Dr. Abraham A. Brill and Dr. and Mrs. John Thelberg have sailed for Europe.

New Pavilion for Measles.—The Health Department will erect a pavilion for the isolation of measles at a cost of more than $200,000 on the grounds of the Willard Parker Hospital, at the foot of East Sixteenth Street.

Money for Charity.—The contest against the will of Walter Duryea has been withdrawn and the terms of the will will be complied with. Under this will the Nassau Hospital at Mineola receives $25,000 outright and $75,000 when the sister of the testator dies; the Children's Home at Mineola, $5,000; Roosevelt Hospital, $15,000 to establish three memorial beds; Montclair Convalescent and Fresh Air Home, $2,000. Other philanthropic institutions were also remembered.

Rabies Shows Increase.—Since January the Health Department has had examined 3,469 animals for rabies, and fully 10 per cent. have been found to have the disease. For the corresponding period in 1910, 3,010 were examined and 172 cases of rabies were found. Besides the 279 people who have received Pasteur treatment in the city since January, 420 persons outside the city have been treated by the Health Department. Last year 189 received treatment in the city, and 437 persons outside.

Decline in Typhoid.—For eight weeks ending September 2, 1,042 cases of typhoid fever have been reported to the Health Department from all boroughs of the city. This is an increase of 241 over the cases reported in 1910. During the week ending September 2, only 121 cases were reported as against 158 for the same week last year. This seems to indicate that a normal point has been reached in the epidemic. The Health Department declines to go into the probable cause of the epidemic this summer except to say that the water-supply, is not responsible for the outbreak. Ten milk companies which were under suspicion in connection with the epidemic on the upper West Side have shut off their supplies.

New York Milk Committee Plans New Work.—The Committee for the Reduction of Infant Mortality of the New York Milk Committee feels that the results attained by the united efforts of the various agencies in combating infant mortality due to diarrheal diseases now plans to turn its attention to congenital troubles, which next to diarrheal diseases, cause the largest infant mortality. The committee has taken charge of 1,000 expectant mothers and will endeavor to bring all of the community's resources to bear which may enable the mothers to give birth to well children strong enough to combat the numerous ills that await them. An arrangement has been made with the Russell Sage Foundation which will detail a special nurse who will devote all her time to this work. The mothers will be given a careful physical examination and will be instructed in methods of proper care of themselves preparatory to the coming of the children. When an expectant mother is forced to overwork help will be provided for her. Arrangements will be made for these women to go to the hospital and no midwives will be permitted to attend these cases. After confinement adequate care will be provided for the mothers and the children will be referred to proper milk stations. Last year about one-third of all infant deaths occurred during the first month of life and the committee will endeavor to prove that this percentage can be materially lowered. If this proves to be true an active campaign along these lines will be instituted next summer.

NORTH DAKOTA

District Association Meeting.—At the annual meeting of the Grand Forks District Medical Association held in Grand Forks the following officers were elected: President, Dr. Anders A. Westeen, Grand Forks; vice-president, Dr. John Montgomery, Ardoch; secretary, Dr. George M. Williamson, Grand Forks; treasurer, Dr. Charles S. Marsden, Carrington, and delegates of the State Society, Drs. Henry H. Healy, Grand Forks, and John S. Countryman, Grafton.

PENNSYLVANIA

Hospital Buys Farm.—The Kensington Dispensary for the Treatment of Tuberculosis purchased a farm in Upper Providence Township for $6,994.08.

Personal.—Dr. John A. McKenna, of Lansdowne, has returned from Europe.——Dr. Malcolm Z. Gearhart, Reading, who was operated on for appendicitis in the Jefferson Hospital at Philadelphia, is reported to be improving.

To Prosecute Unregistered Midwives.—At a meeting of the Clarion County Medical Society on July 25, resolutions were passed that the society act as prosecutor in all cases of unregistered midwives, the evidence to be furnished by any member of the society.

Endorses Wiley's Work.—Blair County Medical Society at its meeting in Altoona, August 23, adopted resolutions expressing its belief in the professional skill of Dr. Harvey W. Wiley, extending their moral support in his efforts to protect human life and hoping that "no possibility of technical fault may cut short his most useful career."

Hospital Fire.—A fire caused by crossed electric wires in the Panther Creek Valley Hospital resulted in one death and $10,000 damage. The Reading and Lehigh Coal and Navigation Companies sent special trains to convey fire companies to the scene and the flames were subdued after the roof had been destroyed and the third story gutted. Thirty-eight patients were rescued.

Censorial District Meeting.—The sixth annual meeting of the Fifth Censorial District Medical Society was held at Waynesboro July 25, and the following officers were elected: president, Dr. J. Burns Amberson, Waynesboro; vice-president, Dr. Harry A. Spangler, Carlisle; secretary and treasurer, Dr. George E. Holtzapple, York. The next meeting will be held at Mount Holly Springs, in July, 1912.

Philadelphia

Personal.—Dr. Walter L. Pyle has recently returned from Europe.——Drs. John F. McCloskey and Fred Stahley were seriously injured when their automobile ran into a tree which had been blown across a drive in West Fairmount Park in a storm August 18.

Quarantine on Brandenburg Lifted.—Twenty-nine hours after quarantine had been placed on the steamer *Brandenburg* because of the illness of a passenger with symptoms suspiciously like cholera, the steamer and its passengers were released as cultures taken showed a negative result.

Hospital Sells Building.—The Methodist Hospital has sold 1015-17-19 Chestnut Street, a lot 69x180 feet, for a consideration reported to be $425,000. This building, together with the Chestnut Street Opera House adjoining, was bequeathed to the Methodist Hospital about 15 years ago by the will of Colonel Bennett.

Playground Work Ended.—The public school playgrounds, conducted in the yards of the public schools and under the direction of the board of education closed August 31. The grounds were open six days of the week for eight hours each day with at least a principal and a teacher in attendance. Beside healthful supervised play, instruction in small arts, such as basket weaving, hammock weaving, sewing, etc., was given. Hammocks almost without number were made and given to hospitals, recreation piers and municipal playgrounds in various parts of the city.

SOUTH DAKOTA

Personal.—Major Hans M. Finnerud, M. C., N. G., S. Dak., Watertown, has been made chief surgeon with the rank of colonel.——Dr. John R. Nilsson, Lead, who was operated on recently in Omaha, has recovered.

TENNESSEE

Commercial Men Form Health Association.—The Tennessee Commercial Men's Health Association, organized at Chattanooga August 14, with an initial membership of more than two hundred.

Physicians Victimized.—The police arrested in Chattanooga, August 26, a man giving his name as J. D. Cooper, who is said to have posed as a doctor and to have victimized several local physicians by inducing them to endorse his checks.

President to Lay Hospital Cornerstone.—Excavation for the Lincoln Memorial University Hospital, Knoxville, the cornerstone of which will be laid by President Taft, September 18, has been begun. The building will be four stories in height and will cost about $13,000.

TEXAS

Money for Hospital.—By the will of the late John W. Gates $150,000 is devised to the Mary Gates Memorial Hospital, Port Arthur.

Personal.—Dr. John O. McReynolds, Dallas, has returned from England.——Dr. Albert W. Nash, Dallas, has been appointed health officer of Nash, succeeding Thomas B. Fisher, resigned.——Dr. Albert Woldert, Tyler, sustained a heavy loss by the burning of a building owned by him in Plainview, August 22.——Dr. Joseph C. Darracott, San Antonio, for several years physician at the Schaefer Hospital, has resigned and will be located in Deming, New Mexico.

Two Tuberculosis Colonies.—The State Department Commission for the selections of sites, erection of building, etc., has made sufficient progress to insure the completion of at least one colony within the next year. It has purchased a tract of land on the Concho River near Carlsbad on which a colony will be established and the other is to be located at the old Fort Clark reservation. The specifications call for the establishment of a colony to cost about $50,000, and to accommodate at least sixty patients.

UTAH

Personal.—Dr. Elmer E. Hinckley, Provo, has returned from Europe and will practice in Salt Lake City.——Drs. Clarence M. Clarke, Provo; Albert G. Stoddard, Spanish Fork; Horace C. Holbrook, Lehi; Frank E. Winter, Payson, and Philemon M. Kelly, American Fork, have been appointed members of the board of health of Utah County.

WEST VIRGINIA

State Board Election.—At the annual meeting of the State Board of Health, Dr. Robert E. Vickers, Huntington, was elected president, and Dr. Hugh A. Barbee, Point Pleasant, was reelected secretary for the firth time.

Personal.—Dr. Albert E. Nolte has been appointed health officer of Wheeling, vice Dr. Charles A. Barlow, resigned to become superintendent of the State Hospital for the Insane, Spencer.——Drs. T. Jud McBee, Elkins, and Irvin Hardy, Davis, purchased the City Hospital, Morgantown, and will tear down the old building and erect a hospital on the site.

WISCONSIN

Improvements at State Sanatorium.—The state board of control, on August 25, awarded contracts amounting to nearly $10,000 for improvements at the State Tuberculosis Sanatorium, Wales.

Personal.—Dr. C. William Stoelting, Oconto, has recovered from his recent operation for appendicitis.——Dr. Howard D. Eaton, who has been practicing in Chihuahua, Mexico, for seven years has returned and located in Shopiere.

Sanatorium Agreement.—At a conference held August 23 between representatives of the county and city of Milwaukee to devise a method of cooperation in the fight against tuberculosis, an agreement was reached whereby the county will lease from the city the Greenfield Sanatorium at Wauwatosa. The institution is to be under the supervision of Dr. George H. Ernst, at present superintendent of the city tuberculosis institutions. New buildings are to be erected which will increase the capacity of the institution to 100.

GENERAL NEWS

Antityphoid Vaccination Compulsory.—By recent order of the Secretary of War, on recommendation of the surgeon general, antityphoid vaccination is made compulsory for all officers and men of the army under 45 years of age.

Rock Island Surgeons Meet.—The ninth annual meeting of the Surgical Association of the Rock Island Lines will be held in Colfax, Ia., September 13 and 14, under the presidency of Dr. Samuel C. Plummer, Chicago, chief surgeon of the system.

Pay of the Hospital Corps Increased.—The recommendation of the surgeon general of the army that the pay of noncommissioned officers of the Hospital Corps be advanced to the scale paid non-commissioned officers in other staff departments, has been approved by the general staff.

Mouth Hygiene Meeting.—At the meeting for organization of the National Mouth Hygiene Association, held in Cleveland, O., Dr. Eugene H. Porter, commissioner of health of New York City was made first vice-president; Dr. William A. Evans, former commissioner of health of Chicago, second vice-president, and Dr. Oscar Dowling of Shreveport, secretary of the Louisiana State Board of Health, third vice-president.

American Life Convention.—The medical section of the American Life Convention will hold its annual meeting in Pittsburgh, September 20, the day before the opening of the general *convention*. Among the papers announced to be read are "Transmission of Tuberculosis Through Fetal Life," by Dr. Harold C. Miller, medical director of the Pittsburgh Life and Trust Company; "The Healed Tuberculous Lesion from a Life Insurance Standpoint," by Dr. G. W. Parker, medical director of the Peoria (Ill.) Life Insurance Company; "Blood-Pressure," by Dr. Henry Wireman Cook, medical director of the Northwestern National Life Insurance Company, and "Nervous Diseases as Applied to Life Insurance" by Dr. John S. Turner, medical director of the Southland Life Insurance Company. Medical directors, examiners, actuaries and officials of life insurance companies are invited to attend this meeting and to participate in the discussion. Dr. Frank L. B. Jenney, Chicago, is secretary of the section.

International Manifestation in Honor of Sir Patrick Manson.—A committee has been organized to do honor to the one who has been so largely responsible for the progress realized in the knowledge of diseases of tropical countries, Sir *Patrick* Manson, the movement for the international manifestation having been started in France. The announcement states that the creation of schools or institutes of tropical medicine is also due to his initiative genius. It is proposed to present him with a portrait medal, in gold, the work of Dr. Paul Richer, professor of anatomy at the Beaux-Arts in Paris. Subscriptions may be sent to Asselin and Houzeau, publishers of the *Archives de Parasitologie*, place de l'Ecole de Médecine, Paris, France, or to Mr. James Cantlie, 140 Harley St., London, W., England. A bronze replica will be sent to each one who subscribes $5 and a silver one for twice this subscription or more. The forty-five members of the committee represent the leading countries of the globe: the list includes Drs. W. H. Welch, G. N. Calkins, F. G. Novy, C. W. Stiles and H. B. Ward of this country.

LONDON LETTER

(From Our Regular Correspondent)

London, Aug. 26, 1911.

The Falling Birth-Rate

The lowest birth-rate on record has once more been reported. For the quarter ending June, 1911, the births were in the proportion of 25 per thousand of the population, which is 3 below the mean birth-rate in the preceding ten second quarters and the lowest recorded since the establishment of civil registration. The death-rate for the quarter was also unusually low—13.3 per thousand, which is 1.3 below the mean death-rate in the preceding second quarters. Infant mortality was in the proportion of 91 per thousand births under the age of one year. This is 15 below the average of the preceding ten quarters and is the same as that recorded in the second quarter of last year, which was the lowest recorded. The marriage rate also was unusually low—10 per thousand of the population against an average of 11.4 in the preceding 10 years.

The Antituberculosis Campaign

A movement is in progress for the establishment of tuberculosis dispensaries, of which *there* are a *few* in *London* and other parts of the country. One of the main features of the treatment is the administration of tuberculin. It is claimed that as the dispensaries receive the cases earlier than sanatoriums and their upkeep is much less expensive they are a better means of coping with the disease. Moreover, there is not sanatorium accommodation in the country for a tenth of the cases of tuberculosis. On the other hand, some question the excellent results which are claimed for the dispensaries. The diagnosis is often based on the reaction to tuberculin. But, as it has been shown that a large proportion of healthy soldiers react to tuberculin, the reality of the alleged cures is questioned. An appeal is now being made for $500,000 to establish tuberculosis dispensaries in London and the response has been encouraging. At the recent tuberculosis conference Mr. Waldorf Astor read a very important paper on the cost of tuberculosis. He showed that when the insurance scheme now before Parliament is fully developed some $50,000,000 will be spent every year on the sick. Of this over $15,000,000 will be required on account of tuberculosis alone. In Ireland, a country in which tuberculosis is very prevalent and in which the disease has shown no such decline as has been manifested in *England in recent years*, a *gratifying improvement* is at last apparent. The death rate from tuberculosis has fallen from 2.7 per 1,000 in 1907 to 2.6 in 1908, 2.4 in 1909, and 2.3 in 1910.

The Study of Pellagra

The second field commission for the investigation of pellagra has just left London for the Continent. It is composed of Dr. Louis *Sambon, lecturer*, London School of Tropical Medicine and parasitologist to the Wellcome Physiological Research Laboratories, and Dr. Albert T. Chalmers, lecturer on pathology and animal parasitology, Ceylon Medical College. These two members of the commission will be joined *en route* by Professor Haase, of Memphis, U. S. A., Dr. Cole, of Atlanta, U. S. A., and Dr. Martinez, of Yucatan, Mexico. The commission will proceed to the study of the epidemiology and etiology of pellagra in Hungary, the Austrian Tyrol, Spain, and the south of France. The governments of Austria-Hungary and of Spain have shown interest in the work and have granted every facility for prosecution of the study. Mr. H. S. Wellcome defrayed all the expenses of the present field commission. The work in Italy in the spring of 1910, by Dr. Louis Sambon, has gained many converts to the belief that pellagra is not due to eating *damaged* maize, but to a parasitic disease conveyed by the bite of a fly—a belief which has been seriously taken up by several observers, particularly in the United States. The field commission is to visit the pellagra-infected districts of Transylvania, the Austrian Tyrol, and the Asturias in Spain.

The Great Railway Strike

The railway strike which has happily ceased after a few days is an event unparalleled in our industrial warfare and threatened to produce quickly suffering of appalling magnitude. All the great railway lines in the kingdom, with one exception, were held up and the starvation of the great towns was only a matter of days. Another evil was the insanitary condition due to the impossibility of removing garbage. In Liverpool, where the greatest disorder occurred, the last difficulty was considerable and the death-rate was doubled. Even the hospitals had to complain to the Lord Mayor, stating that they would have to close their doors if the necessary supplies were not allowed to pass through by the strikers. In London also some of the hospitals suffered great inconvenience and one had to curtail its work on account of shortage of supplies. One issue of the *British Medical Journal* had to be reduced in size as the necessary paper could not be obtained.

Epidemic of Cerebrospinal Meningitis

A serious outbreak of cerebrospinal meningitis has occurred in Devon and Cornwall; 30 cases scattered throughout various districts have been reported and fresh cases are occurring daily. Five deaths have already taken place.

BERLIN LETTER

(*From Our Regular Correspondent*)

Berlin, Aug. 18, 1911.

The Heat Wave

The intense heat during the last weeks has claimed many human victims, a condition which to date has been known to us only from American newspapers. In Berlin and elsewhere in Germany deaths from sunstroke have been reported daily and also numerous deaths from drowning. Thus, in the province of Silesia, during the last three weeks not less than ninety-two persons drowned while bathing, and twenty-eight died from heatstroke.

Congress for Race Hygiene

Of the many congresses which have been held in Dresden this summer, during the International Hygiene Exhibition, the Congress for Race Hygiene had a special interest, as a special race hygiene section in the exhibition had been arranged by Professor von Gruber of Munich, who lectured at the congress. He made clear that for each new generation a considerable number of the individuals are failures and that only a few attained high physical and mental standards. If an elevation of the average human being could be accomplished, a bettering of human conditions could be produced. The last century was under the sway of the dogma that all men are born equal; this had led to an overvaluation of the environment. It is certain that the environment is sometimes of great importance to the development of the individual; this is shown, for instance, by the variation of plants induced by changes in the conditions of growth. As a whole, however, the improvement, the social reforms, cannot essentially improve the race, because such improvements cannot be inherited and because the environment can never develop in an individual any characteristic the germ of which was not implanted by heredity The environment can often suppress these inherited tendencies, but it cannot add anything to them. Much more important than the environment is the inherited complex of tendencies. Race hygiene is needed to promote the regeneration of the strong and to check that of the weaker elements.

The Swedish social economist, Professor Fahlbeck, attacked energetically the so-called neomalthusianism. He characterized the efforts to check the natural growth of the population as agitation for race-suicide.

Sick-Benefit for Mine Workers

Among the labor organizations, the Westphalian-Rhenish Mine Workers' Central Union occupies a remarkable position by reason of its large membership and its activities. The report for 1910 gives a membership of about 350,000. The total number of cases of disease entailing inability to work numbered about 212,000, as against 226,000 for 1909. In frequency, rheumatism of the muscles and joints stands first; diseases of the digestive organs come next; the number of cases of appendicitis increased from 459 to 500. The report says that "this higher figure can probably be explained by the fact that appendicitis is in the foreground of medical interest and essential improvement has been made in early diagnosis. It is improbable that the increasing number of these cases offers a support for the claims of the vegetarians to the effect that it is due to the increase in the consumption of meat." There were 704 fatal accidents due to the employment, including one case of gas poisoning. The number of injuries due to mechanical causes shows a continued increase, reaching the number of 57,179, as against 54,799 in the preceding year, but the number of deaths resulting from these accidents shows a considerable decrease, a fact undoubtedly due to the improvements in mining technic. The Bochum central organization has 800 branch offices and has two large hospitals, one for diseases of the lungs and one home for convalescents. During the year, 337 general practitioners and eighty-six specialists took care of the sick, and for the treatment of the sick members about \$4,000,000 (16,400,000 marks) was expended, of which about \$2,500,000 (9,700,000 marks) was paid as sick-benefit, about \$800,000 (3,200,000 marks) was hospital expenses, about \$350,000 (1,500,000 marks) for medicine, and about \$500;000 (2,000,000 marks) as fees for physicians. This organization provides for sick-benefits and old age and invalid pensions. The income of these three departments amounted in 1910 to about \$14,000,000 (56,100,000 marks), as compared to \$13,500,000 in 1909, and the expenses were \$10,000,000, as compared to \$9,500,000 in 1909. The balance-sheet of the three departments totaled \$43,000.000 (173,000,000 marks), as compared to \$35,500,000 (150,000,000 marks) in 1909.

End-Results in the Treatment of Tuberculosis

The official insurance bureau of the Hansa cities (Lübeck, Bremen and Hamburg) has published a report of the results *obtained in the thirty-three sanatoriums supported by this* bureau. In this report a special interest is attached to the figures dealing with the ultimate outcome of the treatment of pulmonary tuberculosis. Of the 37 male patients treated in the sanatoriums during 1895, suffering from lung phthisis, 56 per cent. had died before the end of 1910; 8 per cent. were unable to work and 13 (36 per cent.) had full earning capacity, but three in this group had taken more than one course of treatment. Of the 19 female patients treated in 1895, 5 (28 per cent.) had died before the end of 1910; 5 per cent. were unable to work, and 12 (67 per cent.) were fully able *to work. Two of the latter had taken repeated treatment.* Of the 99 male patients treated during 1896, 33 (35 per cent.) had died; 5 (5 per cent.) were incapacitated; 52 (56 per cent) were fully able to work; of the latter, 17 (18 per cent.) had taken repeated treatment, and 4 (4 per cent.) were only partially able to work. Of the 47 female patients treated during the same year, 4 (9 per cent.) had died; 1 (2 per cent.) was unable to work; 30 (68 per cent.) were able to work, of whom 7 (16 per cent.) had taken repeated treatment; 9 (21 per cent.) were partially able to work. Of 164 male patients treated during 1900, 39 (25 per cent.) had died before the end of 1910; 12 (8 per cent.) were unable to work; 84 (53 per cent.) were fully able to work; of these, 23 (15 per cent.) had taken repeated treatment; 22 (14 per cent.) were only partially able to work. Of the 132 female patients, 15 (12 per cent.) had died; 11 (9 per cent.) were unable to work; 69 (57 per cent.) were able to work, of whom 24 (20 per cent.) had taken repeated treatment; 26 (22 per cent.) were partially able to work. From the standpoint of the ultimate outcome, it is important to note the causes of the disease in the individual patient. The cases are classified in four groups:

1. Slight infection, limited to a small area of one lobe, and especially to the apex.
2. Cases in which the infectious process exceeded the limitations of Group 1; involving one or both sides without any pronounced dulness or cavity formation.
3. Those showing consolidation of one or more lobes or signs of cavity formation, or pronounced tuberculosis of the larynx.
4. Protracted pleurisies or suspicious catarrh of the larynx without any pronounced findings in the lungs.

The total number of male patients belonging to Group 1 who were treated more than four weeks in the sanatoriums during the years 1895 to 1904 were 471, of whom 117 (25 per cent.) had died before the end of 1910; 25 (5 per cent.) were unable to work; 297 (63 per cent.) were fully able to work; 32 (7 per cent.) were partially able to work. Of the parallel group of 441 female patients, 48 (11 per cent.) had died; 26 (6 per cent.) were unable to work; 293 (66 per cent.) were fully able to work, and 74 (17 per cent.) were only partially able to work.

Of those belonging to Group 2, 461 were male patients, of whom 141 (31 per cent.) had died; 36 (8 per cent.) were unable to work; 240 (52 per cent.) were fully able to work, and 44 (9 per cent.) were partially able to work. Of the 227 female patients, 28 (12 per cent.) had died; 15 (7 per cent.) were incapacitated; 151 (66 per cent.) were fully able to work, and 33 (15 per cent.) were partially able to work.

In Group 3 were 107 male patients, of whom 70 (65 per cent.) had died; 8 (7 per cent.) were unable to work; 23 (22 per cent.) were fully able to work; 6 (6 per cent.) were only partially able to work. Of 34 female patients belonging to this group, 20 (59 per cent.) died; 4 (12 per cent.) were unable to work; 9 (26 per cent.) were fully and 1 (3 per cent.) only partially able to work. Group 4 offers no special interest.

The percentages of male patients who recovered so as to be able to work were in Groups 1, 2 and 3, respectively, 52.5, 42.4 and 4.1; for the women the proportions were 63.7, 32.8 and 2 per cent.

The influence of age, the duration of the disease before treatment and the heredity were also recorded. Of the male patients reexamined in 1910, 306 had been between 15 and 25 years of age; of these, 87 (28 per cent.) had died; 6 (2 per cent.) were unable to work; 194 (63 per cent.) were fully able to work, and 19 (7 per cent.) were partially able to work. In the parallel group of 483 female patients, 63 (13 per cent.) had died; 22 (4 per cent.) were unable to work; 332 (69 per cent.) were fully and 66 (14 per cent.) were partially able to work. Aged from 25 to 50 years were 698 male patients, of whom 217 (31 per cent.) had died; 55 (8 per cent) were unable to work; 364 (52 per cent.) were fully and 62 (9 per cent.) were partially able to work. In the parallel group of 226 female patients, 34 (15 per cent.) had died; 22 (10 per cent.) were unable to work; 128 (57 per cent.) were fully and 42 (18 per cent.) were partially able to work. The report of the patients over 50 years old offers no special interest.

The duration of the disease before treatment had been in 341 male cases from one to six months; of these patients 87 (25 per cent.) had died before the end of 1910; 17 (5 per cent.) were unable to work; 211 (62 per cent.) were fully able to work; 26 (7 per cent.) were partially able to work. Of the parallel group of 172 female patients, 20 (12 per cent.) had died; 4 (2 per cent.) were unable to work; 126 (73 per cent.) were fully and 22 (13 per cent.) were partially able to work. The duration of the disease in 344 male patients had been from six to twenty-four months; of these patients 115 (33 per cent.) had died; 16 (5 per cent.) were unable to work; 191 (56 per cent.) were fully and 22 (6 per cent.) were partially able to work. In a parallel group of 238 female patients, 33 (14 per cent.) had died; 21 (9 per cent.) were unable to work; 147 (62 per cent.) were fully and 37 (15 per cent.) were partially able to work. In 234 male patients the duration of the disease before treatment was from two to six years; of these patients, 82 (35 per cent.) had died; 24 (10 per cent.) were unable to work; 103 (44 per cent.) were fully able to work, and 25 (11 per cent.) were partially able to work. In a parallel group of 187 female patients, 26 (14 per cent.) had died; 8 (4 per cent.) were unable to work; 119 (64 per cent.) were fully able to work, and 34 (18 per cent.) were partially able to work. About the same percentages are evident with patients who had had the disease from six to twelve years before treatment. From this it can be concluded that long duration does not necessarily mean a less favorable prognosis.

An inherited taint had been noted in 274 male patients, of whom 86 (31 per cent.) had died; 19 (7 per cent.) were unable to work; 147 (54 per cent.) were fully and 22 (8 per cent.) partially able to work. In a parallel group of 303 female patients, 42 (14 per cent.) had died; 23 (8 per cent.) were unable to work; 192 (63 per cent.) were fully and 46 (15 per cent.) were partially able to work. No inherited taint could be traced in 656 male patients, of whom 193 (29 per cent.) had died; 38 (6 per cent.) were unable to work; 374 (57 per cent.) were fully and 51 (8 per cent.) were partially able to work. In a parallel group of 270 female patients, 48 (13 per cent.) had died; 19 (5 per cent.) were unable to work; 244 (66 per cent.) were fully able to work, and 59 (16 per cent.) were partially able to work. These figures seem to prove that the so-called inherited taint does not necessarily entail a special lack of resistance to tuberculosis. Such persons do not succumb to it any more readily than those free from such heredity.

Centenary of the University of Breslau

On August 1 and 2 was celebrated the centenary of the founding of the University of Breslau. One year after the founding of the University of Berlin, the University of Frankfort on the Oder, which was only a few miles from Berlin, moved to Breslau on account of the rapid growth of the Berlin institution and the competition it involved. Although the University of Breslau, like the University of Berlin, was founded at a time when Prussia was depressed by the Napoleonic wars, this former institution also was soon to make a remarkable progress, and especially in the medical faculty there developed a school rich in research and important teachings. During these hundred years many prominent men, who have made valuable contributions to medicine, have held positions in the Breslau medical faculty. Among these may be mentioned the physiologists Purkinje and Heidenhain, the internists Frerichs, Biermer and Kast, the surgeons Middeldorpf and Mikulicz, the gynecologist [illegible] logic anatomists Cohnheim and Ponfi [illegible] Foerster, the neurologist Wernicke, and Haeser the professor of history of medicine. As is well known, it was to the famous botanist of Breslau, Ferdinand Cohn, that Robert Koch submitted his first culture of the anthrax bacillus; Koch intended at one time to take up residence in Breslau but gave up the idea for material reasons. On the occasion of the centenary, several professors of other faculties and many especially meritorious men were created honorary doctors by the medical faculty. Ehrlich, who is a Silesian by birth, also received an honorary degree from the philosophical department (equivalent to our arts and sciences department).

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Aug. 21, 1911.

Diseases of Household Servants in Comparison with Other Workers

At present, a union of household servants is in preparation in this country. One of the earliest results of the movement is the information obtained in regard to the distribution of disease among this part of the population. Hitherto, the conditions have been regarded by some as favorable, while others thought them very bad. Altogether, only few such investigations and investigators were known. Certain affections are very frequent. Thus in Vienna, anemia, disorders of the stomach, rheumatism and troubles of the sexual organs are the most frequent, in the order mentioned. Anemia is readily explained by the long stay in badly ventilated rooms and the rare walks in fresh air, as well as by the insufficient amount of sleep; sometimes the quantity of food is insufficient. Cooks suffer in their stomachs because of too frequent tasting of the foods they are preparing. Rheumatic affections are very common among all servants, partly on account of the frequent exposure to cold and bad weather, without sufficient protection, partly from working in unhealthy kitchens, washing kitchens and sculleries. A frequent complaint of servants is static flat-foot with varicose veins of the legs. Affections of the lungs are less frequent than one would expect in Vienna. It seems that the inherited constitutions of the servants—mostly daughters of the healthy rural districts—protect them to a great extent; their health statistics are much better than those of, for instance, shop assistants, typewriters and office girls. The reports of the Vienna Krankenkasse concerning the latter group show that within one year more than 13 per cent. of the members have suffered from affections of the respiratory organs, lasting more than three days, while for house servants the figures are found to be about half of that. The alimentary canal was affected in 9 per cent. of the latter, while in 11 per cent. of the shop and office girls, the conditions of nourishment were also decidedly in favor of the house servants. Worst off is the factory girl, who not only is often underfed but is also exposed to much more danger of physical and moral nature. Illegitimate births are most frequent among this class of workers; the house servants come next in this respect, while the third group only rarely contributes to this item. A remarkable fact is the relative frequency of nervous diseases and neurasthenia, or rather hysteria, among the housemaids; one would not suppose that fully 2 per cent. of all the servants in this group are classified as victims of such diseases. Surgical diseases, except panaritium, bursitis patellaris and dental periostitis, are not frequent among servants, while the factory girls are prone to various factory accidents.

Opposition to Tuberculosis Sanatoriums

The munificence of a wealthy philanthropist has placed at the disposal of the Society for the Care of Tuberculous Patients the necessary funds for erecting, at various places, sanatoriums for tuberculous persons capable of recovery. One of these institutions devoted to the treatment of children, in the incipient stage of the disease, was to be built at Semmering, the well-known health resort in the mountains south of Vienna. Against this project a vehement opposition has arisen, mostly from the owners of other sanatoriums at Semmering, as well as from other persons who ought to know better. It was spread broadcast that such an institution would be a menace to the health of the villagers and other inhabitants of the famous mountain-range, and even the municipality of Vienna protested against the erection of such a sanatorium there, because it would "spoil the air and no longer offer the strangers and tourists a pleasant recreation ground." In vain, the medical men pointed out that the danger of infection did not exist, that the presence of such institutions is an urgent necessity for the national welfare and health; the interests affected by the plan were more powerful than any other consideration, and the philanthropist has been forced to reconsider his generous offer. It is probable that he will also have to cancel some other plans. This loss to public welfare will not be compensated quickly.

A Home for the Vienna Medical Organizations

Apart from the Gesellschaft der Aerzte, no medical organization of this city owns its own home, but all, even the official medical council, have rented flats so that their abodes lack freedom from the whims of landlords and houseowners. It has recently been suggested that a home for all the official, scientific, provident and social organizations and bodies of the profession in this city should be erected. The necessary funds will readily be obtained and the cost of maintenance will be divided among the various bodies. The principal organizations affected by this plan are: the council, the doctors' orchestra, the sick-benefit society, the widows and orphans' society, the economic organization the Doctoren Collegium (a provident society of very considerable means and influence), five scientific medical societies, and also several provident societies in the country districts. It is most likely that a centralization of offices will pave the way for the unification of the societies which, no doubt, would prove a most welcome money-saving proposition, and a strong movement in this direction is manifest. Whatever the result of this movement might be, it is sure that a "doctors' house" is an urgent necessity for us here, not least from an ethical point of view, as an exponent of medical concord.

Spread of Cholera

Cholera is gradually spreading in the southern part of Austria and its hinterland, and sporadic cases appear also in distant places. In Vienna a woman died from it after an illness of four days and there was no clue to indicate the mode of infection in this particular case, in spite of all researches. The army medical corps has been warned to be on the lookout in the affected districts, and maneuvers have been postponed or given up for the same reason. At any rate the public health officers assert that they control the attack and the population is by no means excited or frightened.

Personal

Professor H. Schloffer, who for several years was chief of the surgical clinic in Innsbruck, has been appointed to the equivalent position in Prague (German university).

Professor W. Trendelenburg of Freiburg has been appointed to Innsbruck, as professor of physiology, and Professor Kucera has become extraordinary professor in the University of Lemberg where he will deliver his lectures on hygiene.

Medical Strike in Hungary

The physicians of the workingmen's club in upper Hungary have refused to do any work on the old terms for the club. Physicians from twenty-five other districts joined their colleagues, so that the club had to come to terms with the practitioners at last. This is the first successful medical strike on a large scale in Hungary.

Difference in Intuitive Powers.—G. A. Auden (*Jour. Crim. Law and Criminology*) says that the study of mental defect has taught us that there are some individuals in whom the power of forming a concept from the letter symbols, by which we express words, is lacking (i. e., who are "word-blind"), who are, however, capable of forming correct mathematical concepts from the symbols by which we denote number. There are others in whom the reverse defect is found. These can read fluently, yet they cannot grasp the fact that 3 plus 3 equal 6, because they cannot form a concept of number. We find similarly word-deaf persons and color-blind persons. (There are some grounds for believing that color-blindness is, in part at any rate, central rather than peripheral in origin.) In the same way some of us have no ear to recognize the rhythm of sound which we designate as "tune;" others have a deficient sense of position, and, to use a phrase borrowed from the phrenologist, have no "bump of locality." Indeed such facts as these seem to show that all these faculties are developed in varying degrees in each individual. It seems, therefore, reasonable and logical to regard the capacity of forming a moral concept as analogous, and to believe that this faculty may show all stages of development or be absent.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

THE CHARGE AGAINST DR. WILEY

Extracts From the Testimony Given Before the Congressional Committee

[The charge against Dr. Wiley was nominally formulated by the committee on personnel, composed of Solicitor McCabe, W. M. Hays and C. C. Clark. While most of the charges were actually brought against Drs. H. H. Rusby, L. F. Kebler and W. D. Bigelow, it was made to appear that Dr. Wiley, as Chief of the Bureau of Chemistry, was the individual chiefly concerned. The only actual charge against Dr. Wiley was that he, with Dr. Bigelow, had entered into a secret agreement with Dr. Rusby regarding the rate of compensation that the latter should receive from the government. The committee on personnel submitted a long report to Secretary Wilson, from which we quote a small portion. The part quoted constitutes the whole of the evidence submitted by this committee to prove its contention that Dr. Wiley had entered into a secret agreement with Dr. Rusby. The matter follows:]

THE BASIS OF THE CHARGE

> "On January 23, 1911, Dr. Rusby informed Dr. Wiley that he had agreed with Dr. Bigelow, as being fair and satisfactory, upon the following agreement:
>
> "'This agreement provides that my salary shall amount to $2,000 per year, conditional upon my doing 100 days of seven and one-half hours each. It is understood that if the amount of service should not reach that number of days there would be a pro rata reduction in my compensation.' (Rusby to Wiley, Jan. 23, 1911, E-94.)"

THE CHARGE ANALYZED

[In investigating this point, the following testimony was given by Dr. Wiley before the committee:]

Mr. Floyd: On page 176 of the hearings of July 28, I notice there is a heading: "Facts not controverted"; and on page 177, near the middle of the page, is this statement:

> "Further in a letter of Jan. 23, 1911, to Dr. Wiley, Dr. Rusby states that an agreement had been reached between himself and Dr. Bigelow that his salary should amount to $2,000 per year, with the understanding that he did 100 days' work."

I want to ask you the direct question whether you did or did not enter into any contract with Dr. Rusby whereby he should receive $2,000 for 100 days' work, or any number of days' work?

Dr. Wiley: I did not.

Mr. Floyd: What about that letter? It says that in a letter—

Dr. Wiley: That letter was never sent to me. I never saw it nor heard of it until it was published in these proceedings.

Mr. Floyd: Had you received it at all?

Dr. Wiley: I never had it. It never came to me.

Mr. Davis: The letter in full appears on page 154.

Mr. Floyd: Have you since seen that letter?

Dr. Wiley: Yes, sir; I have seen it published.

Mr. Floyd: The statement that I read would indicate that that was brought to your knowledge, and was an undisputed fact in the case.

Dr. Wiley: Yes, sir. That is false. It was not brought to my knowledge, and I did not know anything about it.

Mr. Floyd: Have you since seen that letter?

Dr. Wiley: Yes, sir.

* * *

Mr. Floyd:—What is your explanation, Doctor, if you have any to make, in regard to that letter?

Dr. Wiley: Dr. Rusby explains it himself on page 185, at the top of the page. In a letter addressed to the Secretary of Agriculture, under date of July 13, 1911, he says:

"I desire to say to you that my letter of Jan. 23, 1911, addressed to Dr. Wiley, was never sent to him, nor, so far as I know, did he ever know that it had been written, until it came out at the hearing. After writing this letter I learned that Dr. Wiley was absent from Washington, and that the letter, if sent, would not reach him. I therefore did not send it, but the copy got into my files, and when you later asked me to send all correspondence bearing on this subject I sent this copy, forgetting that the original had never been sent to Dr. Wiley."

Mr. Floyd: That letter is addressed to Secretary Wilson?

Dr. Wiley: Yes, sir.

Mr. Floyd: Of date of July 13, 1911?

Dr. Wiley: Yes, sir; and it is quoted from on page 178, omitting that part of it which is most important, viz.: that the agreement would not be valid until approved by the department.

Mr. Davis: Page 177.

Dr. Wiley: It is quoted on page 178, in quotations, near the top of the page—the third paragraph. A quotation is made from this letter omitting the first paragraph, which says that "this agreement is not valid until approved by the department" "at Dr. Rusby had no idea of any secret I had not any idea and never knew that been made at all. The committee on personnel knew that I had never seen this letter, because I sent to them a complete list of letters which I had received, and stated that I had never received any personal letter from Dr. Rusby on this subject.

Mr. Higgins: You had no knowledge that this contract was made, then, Doctor?

Dr. Wiley: Absolutely none: and it never was made—no contract of any kind. He says that an agreement was reached with Dr. Bigelow that he would work for that, if approved by the department; not under any other conditions.

Mr. Higgins: But you had no knowledge of these negotiations with Dr. Rusby to get his services as an expert investigator?

Dr. Wiley: I did not have any knowledge at all of them. I asked Dr. Bigelow to find out from Dr. Rusby the smallest salary he would work for, on an annual salary. That is all I asked him to do. I did not know any means by which they reached the $2,000.

Mr. Higgins: You had no knowledge or information about the matter of the exchange of letters, and consultations?

Dr. Wiley: I know they exchanged letters, and Dr. Bigelow came to me from time to time.

Mr. Higgins: But you did not know what they contained?

Dr. Wiley: I did not know what they contained. I never saw the letters.

Mr. Floyd: And you had no correspondence yourself?

Dr. Wiley: I had not a word of correspondence of any kind with Dr. Rusby on this subject.

Mr. Floyd: The letter from which they quote on page 177 and page 178 is a letter of January 23, 1911, which reads as follows:

Dr. Wiley: Which was not sent—which I *never* received.

Mr. Floyd (reading):

Dr. H. W. Wiley,
Chief Bureau of Chemistry, Washington, D. C.

Dear Sir: As a result of considerable discussion and correspondence with Dr. Bigelow regarding some change in the compensation allowed me as pharmacognosist which would make it possible for me to continue in the service, we have agreed upon the following arrangement as being fair and satisfactory, IF APPROVED BY THE DEPARTMENT.

Dr. Wiley: Yes, sir.

Mr. Floyd (reading):

This agreement provides that my salary shall amount to $2,000 per year, conditional upon my doing 100 days of 7½ hours each. It is understood that if the amount of service should not reach that number of days there would be a pro rata reduction in my compensation.

Trusting that this will be satisfactory to everyone concerned,

Very truly yours,

Dr. Wiley: And I should like to say, Mr. Floyd, that any connection I may have had with this alleged contract is based solely on that undelivered letter, which I had never seen, and on a partial quotation from it. There is not a scintilla of other evidence in this hearing that connects me with any such contract in any way.

Mr. Floyd: Did you have any correspondence with Dr. Rusby about this contract?

Dr. Wiley: Not a word; not a word on this subject.

Mr. Floyd: And you had received no letter whatsoever from him?

Dr. Wiley: Never, on this subject.

Mr. Floyd: On this subject; and the letter which they quote from was an unsigned letter, written by Dr. Rusby, but never delivered to you?

Dr. Wiley: Never sent out of his house until he brought it down himself.

Mr. Floyd: And he brought it in response to a call of this personnel board for all correspondence.

Dr. Wiley: Yes, sir. I have here a list of all the letters he sent—all the letters I have ever had from Dr. Rusby—which I sent to this personnel committee.

DR. WILEY CROSSEXAMINED

[The committee on personnel called Dr. Wiley and his associates before them and subjected them to a severe cross-examination. In discussing this investigation the following facts were brought out:]

Mr. Floyd: Did they state to you in that investigation what the charges were against you?

Dr. Wiley: No, sir.

Mr. Floyd: Did you know that any charges were made against you?

Dr. Wiley: I did not.

Mr. Floyd: They did not inform you that they were investigating charges against you?

Dr. Wiley: No, sir.

Mr. Floyd: Did you understand from your appearance there, and the questions asked, what the proceeding was or what it meant?

Dr. Wiley: No, sir; but before they got through I had my suspicions. In the first place, it was held secretly. Every other person had to leave the room. I did not like that. I considered that an insult to me.

Mr. Floyd: When you testified, no other person was allowed in the room?

Dr. Wiley: Then, before they got through, I thought there was something wrong; and so the next day I addressed a letter to Mr. Hays to find out and ask him specifically if there were any charges preferred against me or any member of my bureau. This letter read as follows:

Mr. Floyd: Just read that letter. I should like to hear it.

Dr. Wiley (reading):

Hon. Willett M Hays,
Assistant Secretary of Agriculture.

Dear Sir: I would be very glad if you would furnish me with a copy of any charges, or a summary of charges, presented to the Secretary of Agriculture or to the board of personnel respecting the attitude of the Chief of the Bureau of Chemistry, in regard to the appointment of Dr. H. H. Rusby as an expert pharmacognosist, or to any changes in his title or rate of compensation. Reference was made at the beginning of the hearing on Thursday, April 20, to a certain paper summarizing the charges, but I have not seen that paper nor have I been furnished with a copy. I think it is only just to my bureau to know what charges have been made, if any have been made, and by whom they were made.

Respectfully,
H. W. Wiley, *Chief.*

I will also read Mr. Hays' reply, dated April 24. (Reading:)

Dr. H. W. Wiley, April 24, 1911.
Chief Bureau of Chemistry.

Dear Sir: Referring to your letter of the 22d instant, requesting that you be furnished "with copy of any charges, or a summary of charges, presented to the Secretary of Agriculture or to the board of personnel respecting the attitude of the Chief of the Bureau of Chemistry, or any of the employees of the Bureau of Chemistry, in regard to the appointment of Dr. H. H. Rusby," etc., I beg to advise you that the matter has not been presented to the committee on personnel, in the form of charges. Under date of March 28, Dr. F. L. Dunlap, as acting chief of the Bureau of Chemistry, transmitted a memorandum to the Secretary, with certain exhibits, in relation to the matter referred to. This memorandum and papers were referred by the Secretary to the committee on personnel for investigation and report. In compliance with your request, I have had copies of this memorandum and accompanying papers made, and am forwarding them to you herewith. I am also sending a copy of the stenographic report of the hearing before the committee on personnel on April 20, 1911, at which you and Drs. Bigelow, Kebler and Rusby appeared.

Should you or Drs. Bigelow, Kebler or Rusby desire to submit any further statement in regard to the matters referred to in the papers forwarded, I would thank you to let me have them in writing for the committee on personnel by Friday morning, April 28.

Respectfully,
W. M. Hays, *Assistant Secretary.*

Mr. Davis: Those letters, I may say, are already in the record at pages 159 and 160, marked "F-108" and "F-109." They have already been printed.

Mr. Floyd: You received the opinion and recommendations of the personnel board, did you, in that letter?

Dr. Wiley: No; there was no other opinion in that letter except that.

Mr. Floyd: But did they afterwards send you the proceedings, with their findings?

Dr. Wiley: The hearings, yes; a copy of the hearings.

Mr. Floyd: Did they enclose you the recommendations of the personnel board?

Dr. Wiley: No; not then. I did not get those until two months or more later.

Mr. Floyd: Two months or more later?

Dr. Wiley: Yes. I got them, I think, on the 7th of July.

Mr. Floyd: You got a copy of the recommendations of the personnel board on the 7th of July—two months after that?

Dr. Wiley: Yes; in which they kindly offered me the opportunity to resign my position. Yes; I got that. I am much obliged to them for their courtesy.

Mr. Floyd: Did you receive them before they had been transmitted to the President, or afterwards?

Dr. Wiley: Afterwards; after they had been to the Attorney General.

Mr. Floyd: And to give force to that recommendation it was also accompanied by the opinion of the Attorney General, in which he also kindly gave you permission to resign, did he not?

Dr. Wiley: I will not express any opinion about the Attorney General.

THE POWER OF THE GLUCOSE TRUST

[The peculiarly powerful influence that certain large manufacturing interests exert at Washington was brought out in Dr. Wiley's testimony in connection with the Corn Products Co., commonly known as the "glucose trust." As THE JOURNAL has frequently pointed out, the use of the term "corn syrup" as a synonym for glucose is a direct imposition on the public: first, because "corn syrup" is not a syrup in the common acceptance of the term, and second, because people who are unwilling to buy glucose under its own name should not have it palmed off on them under a euphemistic and misleading name. Dr. Wiley has always maintained that glucose should be labeled glucose, but, as the following testimony brings out, he was overruled by mysterious influences brought to bear at Washington:]

Mr. Higgins: The opportunity was open, Doctor, for an appeal to the Secretary from the findings of the board?

Dr. Wiley: A great many times the interests affected did appeal to the Secretary.

Mr. Higgins: In such cases were they given a hearing?

Dr. Wiley: Yes; they were often given a hearing after the board had come to a decision and the Secretary had approved the decision of the board. One case particularly I have in view where the interests were given a hearing after the board had considered their action, the question of "corn syrup" as a proper label for glucose. The board, after giving a hearing to the parties interested and considering all the evidence, came to a decision, which was very grateful to me, because it was my opinion from the first that the term "corn syrup" was deceptive, and was used only to induce people to buy glucose who would not buy it if it were labeled "glucose," and all the board joined in that decision; it was approved by the Secretary of Agriculture and was sent to the printer and was in galley proof.

Dr. Wiley: At the time that decision was made the chairman of the board (myself) wrote a letter to the president of the Corn Products Co., Mr. E. T. Bedford, informing him of the action that had been taken. After the decision was actually approved an order was issued to suspend its publication—in fact, it was never published—but an exactly contrary decision was subsequently published by the three secretaries as a regulation under the Food and Drugs Act. I know from my own personal knowledge that the Corn Products Co. was very busy: they secured certificates from about thirty prominent chemists of this country, one of whom was afterwards a member of the referee board, to the effect that "corn syrup" was a proper term, and in one case at least I know that money was offered for this opinion to an eminent chemist, who declined to receive it, but informed me of the fact that he had been offered payment to render such an opinion.

Mr. Higgins: You do not mean to say that anybody in the government service was offered money?

Dr. Wiley: No; none of these chemists were in the government service. When I found out this was going on I wrote to all the chemists who were charged with the enforcement of the Food and Drugs Act of the United States, in the various states, and I put the question up to them whether, in the opinion of the food and drug chemists, "corn syrup" was a proper name for glucose, and everyone answered in the negative. They were not offered any money for their opinion by me and I do not suppose by anyone else—

Mr. Higgins: You think, then, experts are sometimes influenced by the size of their fee?

Dr. Wiley: No; I do not say that. I said that in this case one set of experts were offered money and others were not; that is all I said. When Mr. Bedford found out I had applied to the state chemists, he protested to the Secretary of Agriculture against my doing so.

Mr. Floyd: Who did so?

Dr. Wiley: Mr. Bedford, the president of the Corn Products Co.

Mr. Higgins: Protested to whom?

Dr. Wiley: To the Secretary of Agriculture. The Secretary of Agriculture sent me a telegram from Mr. Bedford and asked me to tell him what I had done, and I submitted to him a copy of the questions that I had submitted to the state chemists charged with the enforcement of the Food and Drugs Act. At the same time I prepared a brief on the question, which to my mind was a pretty good piece of work. This brief was furnished to the Corn Products Co., but Mr. Emery, of Wisconsin, the state food commissioner, had the greatest difficulty in getting a copy of it. Finally, I believe he had to apply to a member of Congress to get a copy, and I think he succeeded in getting a copy. He sided with me in this matter, and he had a suit on in his state, for he had ruled that "corn syrup" was not a proper name for glucose, and he wanted my brief, and he finally got it. You can find out from Mr. Emery how much trouble he had in getting it.

Mr. Higgins: He did not have any trouble in getting it after he applied to a member of Congress, did he?

Dr. Wiley: I don't know about that. I know that he finally applied to a member of Congress. The suit was continued in Wisconsin and the lower court rendered a verdict in favor of Mr. Emery; the case was appealed to the Supreme Court and the Supreme Court sustained the verdict that "corn syrup" was not a proper name for glucose, and gave some of the reasons which I had put forward in my brief.

The point I wish to bring out is this, that after the Board of Food and Drug Inspection had come to a decision—after each member of the board had approved it; after the Secretary had approved it and it was in print—it was withdrawn and an entirely different opinion, signed by the three secretaries, was substituted in its place.

Mr. Higgins: Did that remain as the regulation of the department until the Supreme Court reversed it?

Dr. Wiley: It still remains as the ruling and as the law.

WILEY FAVORS THE CONSUMER

[As indicating Dr. Wiley's attitude in all cases affecting the public health and also as showing how he and his associates were hampered in their attempt to make the Food and Drugs Act an instrument of public safety, the following testimony is both interesting and instructive:]

Mr. Davis: The solicitor [McCabe] in the course of his testimony and also in the course of certain of his correspondence, which has been produced before the committee, made some allusion to the fewness of cases affecting the public health that had been before the Board of Food and Drug Inspection and the Bureau of Chemistry. Do you wish to say anything about it?

Dr. Wiley: Yes; I would like to make a statement in that connection. There have been comparatively few cases which you could say directly affected the public health brought to the courts for the reason that the Bureau of Chemistry, under its constitution and regulation, obeys without question the orders of its superior officers, and having been advised, that is, the Bureau of Chemistry having been advised that the use of benzoate of soda in any quantity whatever was harmless, and having been advised that the use of saccharin and the use of sulphurous acid and the use of alum and the use of the other things referred to the referee board were not to be acted upon until the referee board reported, the Bureau of Chemistry was estopped from reporting hundreds and many hundreds—and I may say thousands—of cases of adulteration which it would have done had it been left to its own judgment in the matter.

Mr. Davis: So that as respects benzoate of soda and benzoic acid the ruling of the referee board cut out from the Bureau of Chemistry the consideration of the preservatives, so called, in this connection?

Dr. Wiley: As adulterants and as being injurious to health, yes, sir; absolutely. We have no authority, Mr. Chairman, to pronounce judgment on these cases which we believed were threatening the public health and were adulterations of the worst type.

Mr. Davis: And as respects alum, for instance, and those other questions referred to the referee board upon which action has not yet been taken, your hands are tied until action by the referee board?

Dr. Wiley: We are absolutely paralyzed.

Mr. Davis: I understood you yesterday to say, at least I think it was yesterday or the day before, that as respects alum you endeavored with your colleagues—or was it another substance?

Dr. Wiley: No; alum.

Mr. Davis: I think as respects alum you endeavored with your colleagues to get an understanding that, until the referee board should pass upon the harmfulness or otherwise of that article, prosecutions should be had in the interest of the public health?

Dr. Wiley: I did.

Mr. Davis: And without success?

Dr. Wiley: My only motive, and that which has guided me in every case which I have considered under the Food and Drugs Act, is to give every doubt to the consumer, and I hold that when experts disagree about the harmfulness of these bodies and the matter is referred to a final arbitrating board that the interests of the public health require that these bodies shall be excluded from foods until the board has reported. I think that is the least duty we can do to the public, and that is the duty I have always endeavored to do.

[Next week additional testimony will be published.]

Miscellany

Call of Scientific Age.—The call of the age to health is a call to sacrifice and to service, both personal and public; and the call to service has been the deepening undertone of the call to humanism, all along the ages. Sophocles, in his day, urged it on the Athenians, and Œdipus seizes on public service for his final passionate appeal to the prophet Teiresias for aid against the plague with which the land was cursed: "For in thee is our hope; and a man's noblest task is to help others, by his best means and powers." Our modern cynics may smile at the inconsistency of an age like our own which is constantly preaching the gospel of efficiency, and yet suffers grievously from bad domestic service and bad municipal service; but physicians, at least, do not need to be told that it is one thing to prescribe for a patient and quite another to persuade that patient to follow good advice. The call to life, and to life in this world, is thus the first and fundamental call of the scientific age. And the next is the call to health, i. e., to wholesome and fulness of normal life. It is not merely that we may have life, but that we may have it more abundantly. The first and chief characteristic of science is that it seeks always after Nature, after the normal, i. e., the natural, and looks askance on the abnormal and the super- or subnormal. Hence the call of a scientific age for normal, natural life and healthy living; hence its disapproval of disease, hence its disgust with dirt as a cause of disease, and its belief in public health as well as private welfare.—Sedgwick.

Standard Death-Rates.—Symptoms are abnormal manifestations of life. For example: The average pulse is about 72 beats per minute, and a pulse much over or under that average is abnormal or unusual, and, as a rule, indicates trouble. As with the pulse, so with the other phenomena of life; the average and the normal are nearly always the same. Just as there is an average pulse, an average number of respirations, an average consumption of food, an average amount of waste thrown off, all of which constitute what we regard as the normal, so there is an average number of deaths per year for a given population, an average number of deaths from typhoid, from tuberculosis and other diseases, which constitute normal standards for estimating health or disease conditions in a given community, town or state. Before one can recognize the abnormal he must be familiar with the normal, and before one is prepared to recognize symptoms of disease politic, he must know the average total death-rate and the average death-rate for the different diseases that obtain in a large population. Such death-rates have been collected and tabulated by the more progressive states that have recognized the value of keeping an account with death, so that from a large collection of authoritative statistics, we can find the normal or average death-rate for all diseases combined, or for any particular disease. Fifty-five per cent., or 48,000,000 of the population of the United States, are within the jurisdiction of rigidly enforced registration laws which supply the following statistics: Average annual death-rate from all diseases is 15 per 1,000; death-rate from tuberculosis, 1,675 per 100,000; for typhoid fever, 22 per 100,000; for whooping-cough, 11 per 100,000; measles, 10.2 per 100,000; and for malaria, 2.5 per 1000,000.—W. S. Rankin in *Bull. North Carolina Board of Health.*

Professional and Public Aspect of the Pneumonia Question.—As a plan of procedure in the prevention of the spread of pneumonia, W. J. White suggests (*Dominion Medical Monthly*, August), first of all, the proper segregation of pneumonia patients and their utensils in hospitals; cleaning by sprays and washes of the nose and throat of all who nurse and come in contact with these patients; careful hand washing of nurses and attendants after handling; careful destruction of sputum and other discharges; sterilization of linen of patients; fumigation of rooms after occupancy; and the use of gauze, which can be burned, instead of handkerchiefs. He would also have attached to dispensaries certain nurses who have received special instruction on nursing and preventing the spread of pneumonia, to be sent to all pneumonia cases in home nursing work. He recommends reporting all cases to the health department governing the district where the disease exists, and fumigation of the quarters in which the disease has occurred by the department after the death or recovery of the patient. Finally, the instruction of the public by pamphlets and school lectures on the necessity for keeping the nose and throat clean, especially during winter months; the necessity for controlling the dust of streets by better sprinkling and night sweeping; the evils of bad ventilation in house, public building and school; of alcohol; of badly cooked and poor food; of lack of rest; of worry; of the handkerchief; of the bearing of spitting on pneumonia as well as other diseases; of the increased resistance generated by open-air sleeping; and similar knowledge.

Marriages

Calvert N. DeForest, U. S. P. H. & M.-H. Service, Libau, Russia, to Miss Mabelle V. Taylor of Hoboken, N. J., April 19.

Edwin G. Kyte, M.D., Martinsville, Ind., to Miss Cora Simms, of Shelbyville, Ind., at Indianapolis, August 26.

Chester A. Whitmer, M.D., West Chester, Pa., to Miss Margaret Shafer, at Hagerstown, Md., August 22.

Valentine Vincent Bourke, M.D., East New York, N. Y., to Miss Edith Johnston of Brooklyn, August 15.

James Alexander Kinnear, M.D., Toronto, to Miss Katherine Oswald Laing of Essex, Ont., August 24.

Leonard Lucius Lamb, M.D., Chatsworth, Ill., to Miss Gertrude Snevely of Monon, Ind., August 30.

John Lyte Ressler, M.D., Bird-in-Hand, Pa., to Miss Elizabeth Staub of Millersville, Pa., recently.

Martin H. Mayfield, M.D., Hollis, Okla., to Mrs. Mattie Jackson of Springfield, Mo., August 24.

Charles Wyche, M.D., Kirkwood, Mo., to Miss Miriam G. Crosby of West Line, Mo., August 24.

Murdock M. Kerr, M.D., Calumet, Mich., to Miss Antoinette Priest of Evart, Mich., recently.

Deaths

Brigadier General Charles Ravenscroft Greenleaf, M. C., U. S. Army, retired, a surgeon of brilliant attainments, died at his home in San Jose, Cal., September 3, aged 73.

He was born in Carlisle, Pa., and was graduated from the Medical College of Ohio, Cincinnati, in 1860. At the outbreak of the Civil War he entered the volunteer service as assistant surgeon of the Fifth Ohio Infantry. Four months later he entered the regular establishment, received the grade of captain in 1866, that of major in 1876; was made lieutenant-colonel in 1891, colonel in 1896, was retired in 1902, for age, and was promoted to brigadier general (retired) in 1904.

General Greenleaf's service included the construction and administration of the Mower Hospital, Chestnut Hill, Philadelphia, said to have been the largest military hospital in the world, containing 5,000 beds. After the close of the Civil War he was in the ordinary frontier and garrison service until 1887, when he was ordered for duty in the office of the surgeon general, where he remained until 1893. From this time until the Spanish-American War he was in charge of the medical supply depot, San Francisco, and during this time was professor of public and military hygiene in the University of California.

General Greenleaf introduced the system of personal identification which is still in use in the army, organized the hospital corps of the army, and was the author of "Greenleaf's Manual for Medical Officers," "Greenleaf's Epitome of Trifler's Manual for the Examination of Recruits," which is still standard, and of many monographs on military-medical topics.

Starling Loving, M.D., one of the oldest, best-known and best-beloved practitioners of Ohio, died at his home in Columbus, September 2, from the infirmities of old age, aged 82. He was born in Russellville, Ky., where he received his preliminary education, and graduated in 1849 from Starling Medical College, Columbus, O., which was founded by his uncle, Lyne Starling. For four years thereafter he was engaged in graduate work in Bellevue Hospital, New York City. During the Civil War Dr. Starling served as major-surgeon of the Sixth Ohio Volunteer Infantry. His society membership included the American Medical Association, of which he was first vice-president in 1894-1895, the Ohio State Medical Association, of which he was president in 1882; the Association of American Physicians, and Columbus Academy of Medicine. He became professor of materia medica in his alma mater in 1857, professor of theory and practice of medicine in 1875 and dean of the faculty in 1884. On the merger of the Starling Medical College and the Ohio Medical University in 1907, Dr. Loving became teacher of clinical medicine in the institution. His hospital appointments included those of physician in chief to St. Francis Hospital, consulting physician to Mount Carmel Hospital and the Lawrence Hospital for Women, and a trustee of the Children's Hospital, Columbus.

Jehiel Tuttle Moore, M.D. McGill University, Montreal, 1874; one of the organizers and for thirteen years dean of the Minneapolis College of Physicians and Surgeons; formerly vice-president, acting president and professor of theory and practice of medicine in the medical department of Hamline University, Minneapolis; who in 1886, presented the resolution to the State Medical Society which eventually resulted in the appointment of a medical board by the legislature to regulate the practice of medicine; died at his home in Minneapolis, August 19, from heart disease; aged 62. Forty members of the State Medical Association honored Dr. Moore by attendance at his funeral. Drs. Horatio B. Sweetser and William B. Murphy acted as active pallbearers and Drs. William J. Byrnes, Leo M. Crafts, David O. Thomas, John D. Simpson, John W. Macdonald and Charles A. McCollom were honorary pallbearers.

Alva Winslow Nichols, M.D. Bellevue Hospital Medical College, 1873; of Greenville, Mich.; trustee of the Michigan Asylum for the Insane, Kalamazoo, from 1882 to 1889; secretary of the board of education from 1896 to 1905; local surgeon of the Pere Marquette, New Erie and Great Central railroads; formerly a member of the local pension examining board; for eighteen years a ward supervisor; died at the home of his sister in Grand Rapids, August 22, aged 62.

Walter Owen Ryan, M.D. Washington University, St. Louis, 1882; a member of the American Medical Association and president of the Sangamon County (Ill.) Medical Society in 1909; a prominent practitioner of Springfield and attending physician to St. John's Hospital, but for the last year a resident of Los Angeles; shot and killed his wife and himself at his home in Los Angeles, September 1, while mentally unbalanced.

Henry Gleason Thrall, M.D. Syracuse (N. Y.) University, 1901; of Fayetteville; formerly a member of the Medical Society of the State of New York and the Manlius Physicians' Club; died at the home of his father at Gouverneur, N. Y., August 10, from tuberculosis, aged 34.

Porter Turner, M.D. Hahnemann Medical College, Chicago, 1886; mayor of Elkhart, Ind., from 1898 to 1902; who had suffered for four years from cirrhosis of the liver; died at his home in the Turner Hospital, Elkhart, August 15, from nephritis, aged 59.

John Duke Waller, M.D. Rush Medical College, 1883; a member of the American Medical Association; for five years assistant physician in the Jacksonville (Ill.) State Hospital; died at his home in Oak Park, August 22, from uremia, aged 59.

John T. Myers, M.D. Washington University, St. Louis, 1871; of Petersburg, Ill.; surgeon in the Confederate service during the Civil War; a member of the Illinois State Medical Society; died in St. John's Hospital, Springfield, August 19, aged 73.

James Sullivan, M.D. Yale University, New Haven, Conn., 1875; of Manchester, N. H.; formerly a member of the New Hampshire State Medical Society and local pension examining surgeon; died in Carney Hospital, Boston, August 16, aged 58.

John E. Angstadt (license, Pennsylvania), a veteran of the Civil War; a member of the board of health of Elizabethtown since its organization, and for one term a member of the school board; died at his home, August 18, from senile debility.

E. L. Nix (license, Texas, 1907), a Confederate veteran and later a soldier in the United States Army; for twenty-nine years a practitioner; died at his home in Kennedale, Tex., January 11, from pulmonary tuberculosis, aged 65.

Joseph Hensley, M.D. Hahnemann Medical College, Chicago, 1871; at one time president of the Oklahoma State Homeopathic Medical Society; died at his home in Oklahoma City, August 20, from senile debility, aged 69.

Wendell D. Neville, M.D. Michigan College of Medicine, Detroit, 1884; of Eagle River, Wis.; a member of the State Medical Society of Wisconsin; died in Chicago, August 24, from valvular heart disease, aged 50.

Samuel Morris Weeks, M.D. College of Physicians and Surgeons, New York City, 1853; Nestor of the medical profession of Nova Scotia; died at his home in Newport, August 19, from senile debility, aged 80.

Leon A. Warsabo, M.D. University of Moscow, Russia, 1868; for thirteen years health officer of Coldwater, Mich.; died at his home in that place, August 23, from cerebral hemorrhage, aged 63.

John E. Lockridge, M.D. Medical College of Virginia, Richmond, 1863; of Indianapolis; died recently at the home of his niece in Nevada, Ia., and was buried in Indianapolis August 15.

William Cyprian Cross, M.D. Vanderbilt University, Nashville, Tenn., formerly of Cherokee, Ala.; died at his home in Hatchubbee, Ala., Dec. 27, 1910, from nephritis, aged 54.

D. A. N. Thomas, M.D. Medical College of Georgia, Augusta, 1888; of Jersey, Ga.; was struck by a train near Fowler's Junction, August 20, and died a few minutes later.

George Calvert Stewart, M.D. College of Physicians and Surgeons, Baltimore, 1878; of Alexandria, Va.; died in the Alexandria Hospital, August 16, aged 58.

Henry Herold (license, Indiana, 1897), a veteran of the Civil War; died at his home in Martinsville, May 15, from valvular heart disease, aged 77.

Benjamin A. Thomas, M.D. Starling Medical College, Columbus, O., 1869; died at his home in Rushville, O., August 6, from senile debility, aged 75.

John Ashbel Johnson, M.D. Albany (N. Y.) Medical College, 1877; died at his home in Chateaugay, N. Y., August 12, aged 72.

Correspondence

Contract-Practice

To the Editor:—I wish to say a public word in commendation of the report of the committee signed by Dr. Edward E. Haley on "The Evils of the Contract-System," and published in THE JOURNAL, Aug. 19, 1911, page 674. If any physician has laid his journal aside without reading that report he should look it up and read it. It is the only paper I have read which goes to the heart of the system. Contract-practice, particularly railroad contract-practice, is the most far-reaching evil at work in lowering the dignity and prestige of medical men and their work.

FRANCIS W. GALLAGHER, El Paso, Tex.

Improper Clothing Deforming the Nipples of Young Girls

To the Editor:—My attention was called some years ago to the coincidence of the adoption of a new style of undershirt by women and an increasing number of cases of so-called retracted nipples.

At first, I was somewhat incredulous in the matter and was disinclined to attribute this very serious deformity to what seemed, at first blush, so small a matter as the wearing of undershirts or vests, by growing girls, in which no special provision is made to prevent pressure on their nipples. I had always supposed that retracted, or rather submerged, nipples were due to tight-fitting corsets. Probably both factors are active in causing this deformity.

I find that a belief is cherished among our profession that so-called retracted nipples may be due to faulty or arrested development, like hare-lip or spina bifida. This, I think, is quite erroneous. So far as I have been able to observe the nipples of little girls with undeveloped breasts, they always protrude beyond the surface of the breast. It seems to be only in the rounded breast of considerable development that the nipple is imbedded in the surrounding tissue, so that the front of the breast is often as smooth as a billiard ball. It seems evident that the pressure of the clothing has held the nipple back while the breast has pushed forward and finally surrounded this sensitive little organ.

This question is of such extreme importance that a most careful and painstaking investigation of its every phase should be carried out. Public institutions like orphan asylums and reform schools for girls would seem to afford a fair field for this study. One would suppose that the wearing of undershirts with pockets to receive the breasts is so simple a matter that it could easily be carried out; yet children are heedless and no one seems to take pains to watch them, or to teach them the need of care of these most important structures.

In talking to a mother the other day on this subject, I was surprised to hear her say that she did not know whether her daughter's nipples were retracted or not. She asked her daughter, a young lady of fifteen or sixteen, to show her breasts and in each of them the nipple was apparently firmly imbedded; at all events, its distal extremity was flush with the front of the breast.

The attitude of our profession should be a firm refusal to countenance the marriage of any nippleless woman. Inability to suckle her offspring ought, in law and conscience, to inhibit any woman from marrying. By insisting on this ultimatum and inciting the mothers of growing girls to be extremely watchful in the prevention of this deformity, we may be able to check its apparently rapid and general increase.

The present generation can scarcely hope to live to see reason and common sense prevail in ordaining the fashions of women's dress, but we ought to be able to prevent the mutilations and self-inflicted deformities of the human body, now, alas! so common.

RICHARD COLE NEWTON, Montclair, N. J.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DIET FOR GASTRIC ULCER

To the Editor:—What is Lenhartz' diet for gastric ulcer? What percentage of cures does it show?

M. OYEN, M.D., Ellsworth, Wis.

ANSWER.—Lenhartz' diet was described in THE JOURNAL, June 12, 1909, p. 1943. The reported cases do not yet afford sufficient data for an accurate estimate of the percentage of cures.

THE CORRECT PLURAL OF SPOONFUL

To the Editor:—Which is grammatically correct, "teaspoonsful" or "teaspoonfuls"?

C. F. H., Oklahoma.

ANSWER.—The correct plural of "spoonful" is "spoonfuls." "Three teaspoonsful" would mean three full teaspoons, not three times the quantity held in a teaspoon.

SPLINT FORMULA WANTED

To the Editor:—Can you furnish a satisfactory formula for a good cloth or felt splint, which can be made pliable by heat so that it can be molded to the limb, and which will afterward become hard?

F. S. R.

The Public Service

Medical Department, U. S. Army

Changes during the week ended Sept. 2, 1911.

Mason, George L., dental surgeon, left temporary duty, Fort Leavenworth, Kan., en route to station, Fort Snelling, Minn.

Johnston, James F., lieut., left presidio of San Francisco en route to Whipple Barracks, Ariz., for temporary duty.

Schreiner, E. R., major, relieved from further duty with 1st Cavalry and on expiration of present leave will return to Boise Barracks, Idaho.

Johnson, Thomas H., lieut., will accompany Troop A, 1st Cavalry, from Sequoia and General Grant National Park to presidio of San Francisco. Lieutenant Johnson will then proceed to Fort Baker, Cal., for duty.

[illegible] dental surgeon, on completion of temporary du[illegible] Ariz., will return to Fort Douglas, Utah.

[illegible] captain, granted thirty days' leave of absence.

Mason, George L., dental surgeon, returned to Fort Snelling, Minn., from temporary duty at Fort Leavenworth, Kan.

Richardson, William H., captain, granted leave of absence for two months, with permission to apply for an extension of one month, to take effect about Nov. 1, 1911.

Brooks, William H., major, granted leave of absence for one month.

Birmingham, H. P., colonel, granted thirty days' leave of absence about Sept. 1, 1911.

Ireland, M. W., granted twenty-four days' leave of absence about Sept. 1, 1911.

Smith, William H., lieut., on arrival at San Francisco will proceed to Fort Sheridan, Ill., for duty.

Mount, James E., lieut., relieved from duty at Fort Sheridan, Ill., and ordered to Schofield Barracks, H. T., for duty.

Tuttle, Arnold D., lieut., on arrival at San Francisco will proceed to Army General Hospital, San Francisco, for duty.

Napier, Edward L., lieut., relieved from duty at Army General Hospital, San Francisco, and ordered to Fort McDowell, Cal., for duty.

Hutton, Paul C., major, when services are no longer required at San Antonio, Texas, is relieved from duty at Fort Snelling, Minn., and ordered to Fort Howard, Md., for duty.

Geddings, Edward F., major, relieved from duty at Fort Howard, Md., and ordered to Fort Snelling, Minn.

Ashford, B. K., major, relieved from duty with governor of Porto Rico and will report to the commanding officer, Porto Rico regiment of infantry for duty.

Scott, Thomas E., M.R.C., ordered to active duty and assigned to station at Fort Moultrie, S. C.

A board of medical officers to consist of Col. Louis A. La Garde, Lieut.-Col. Walter D. McCaw, Maj. Powell C. Fauntelroy, Maj. Carl R. Darnell, Maj. Frederick F. Russell, Maj. Charles R. Reynolds, Maj. Paul S. Halloran, Capt. William T. Davis, Capt. Charles F. Craig, Capt. William A. Wickline, Capt. William A. Duncan, Capt. Henry J. Nichols is appointed to meet at the Army Medical School, Washington, D. C., to determine the results of the preliminary examination of applicants for the final examination of candidates from admission to the Medical Corps.

Casper, Joseph, lieut., granted thirty days' sick leave of absence and directed to proceed to the Philippine Islands for duty on Oct. 5, 1911, instead of Sept. 5, 1911.

Hathaway, L. M., captain, leave of absence extended one month.

Eber, Albert H., M.R.C., granted two months' leave of absence, to take effect about Oct. 1, 1911.

Worthington, Joseph A., captain, granted one month and fifteen days' leave of absence, to take effect about Sept. 15, 1911.

Edger, Benjamin J., Jr., major, granted four months' leave of absence when his services can be spared.

Northington, E. G., lieut., granted thirty days' leave of absence about Sept. 2, 1911.

Denton, William, lieut., ordered to Fort Bliss, Texas, for temporary duty.

Stayer, M. C., lieut., reports from duty on transport *Buford* to duty as surgeon on the *Logan*.

Medical Corps, U. S. Navy

Changes during the week ended Sept. 2, 1911.

Mackenzie, E. G., P. A. surgeon, detached from the *Kansas* and ordered to duty at the naval hospital, New York.

Toulon, A. J., asst. surgeon, ordered to duty at the naval hospital, Philadelphia.

Winn, C. K., P. A. surgeon, detached from duty at naval hospital, New York, to duty on *Mississippi*.

Holeman, C. J., P. A. surgeon, detached from duty on *Petrel* to home and await orders.

Robertson, G. E., asst. surgeon, detached from duty on *Mississippi* to duty on *Petrel*.

U. S. Public Health and Marine-Hospital Service

Carter, H. R., surgeon, granted seven days' leave of absence from Aug. 24, 1911.

King, W. W., P. A. surgeon, directed to proceed from Naples to Genoa, Italy, on special temporary duty.

McClintic, T. B., P. A. surgeon, granted ten days' additional leave from Aug. 24, 1911.

McLaughlin, A. J., P. A. surgeon, directed to proceed to Reedy Island quarantine and Delaware Breakwater quarantine on special temporary duty.

Francis, Edward, P. A. surgeon, detailed to inspect the laboratory of the State Board of Health of Georgia, at Atlanta, and the Bacterio-Therapeutic Laboratory, at Asheville, N. C.

Foster, A. D., P. A. surgeon, leave of absence for one month from Aug. 2, 1911, amended to read "one month from August 20,"

Frost, W. H., P. A. surgeon, detailed to make an investigation into the origin and prevalence of typhoid fever in the vicinity of Fort Smith, Ark.

Evans, J. G., A. A. surgeon, granted nine days' leave of absence, without pay, from Aug. 1, 1911.

Falk, Charles C., A. A. surgeon, granted nineteen days' leave of absence from Aug. 13, 1911.

Hamilton, H. J., A. A. surgeon, granted seven days' leave of absence from Aug. 24, 1911.

Nute, A. J., A. A. surgeon, granted twenty-five days' leave of absence from Sept. 3, 1911.

Tappan, J. W., A. A. surgeon, granted seven days' leave of absence from Aug. 21, 1911.

Medical Economics

THE NEW YORK EVENING JOURNAL ON SCIENTIFIC MEDICINE

In a recent issue of the New York *Evening Journal*, Mrs. Ella Wheeler Wilcox contributed an article in which she extolled "mental healing," and predicted that in 100 years "thought will be the acknowledged power used by all reputable physicians to cure and heal humanity."

The *Journal* says editorially that it is unwilling to print the article without a few qualifications, and then makes some criticisms and comments, from which we quote a part:

> "Mrs. Wilcox . . . is right when she criticizes the doctor who, unable to deal with the neurotic young girl, makes of her a morphin fiend, to let himself out of his difficulties, takes money from the girl's father, and in return inflicts the most dreadful curse on her. Such a physician should be put in jail and kept there. . . .
>
> "Mind cures, faith cures, Christian Science, by bringing into play certain forces of the mind, can combat, and sometimes cure, illness caused by a weakened, disorganized mental and nervous condition. It is in substance true, although a little harsh to say, that the modern mental healers 'can cure any disease that you haven't got;' that is to say, that they can cure a disease which is entirely mental and largely imaginary.
>
> "It is untrue and dangerous to say that any mental healing can take the place of a skilful surgeon. Thousands of children are made miserable throughout life because they are not freed from adenoid growths—abnormal developments in the back of the throat which prevent proper breathing. Only the surgeon's knife can remove and cure adenoids. No faith healer, mental healer, Christian Scientist or anybody but a competent surgeon can do that, or ever has done it. Sometimes adenoids may be partially absorbed, extraordinary physical vigor may fight successfully against them. And the placid, happy mental state of the individual who believes in faith healing may help along a good physical condition.
>
> "But you need a surgeon to attend to adenoid growths.
>
> "You need a dentist to attend to your teeth.
>
> "You need antiseptic treatment, or, better still, aseptic treatment, in all surgical operations.
>
> "You need a skilful doctor 'of the old school' in childbirth, and if you have not got one you risk the life of the mother and child—and you ought to be put in jail for doing that. Some faith healers get around the childbirth problem by saying that it is not necessary to have any childbirth, and that if we were sufficiently scientific material births could be eliminated. But that is not very satisfactory when the child arrives.
>
> "The surgeon's knife does slip sometimes. If the surgeon is incompetent he should be driven out of his profession. The plumber's tools slip sometimes and the job is bungled. Such a plumber should be driven out of his profession. Many surgeons and many plumbers lack skill. But that does not justify the silly notion that you can install plumbing in a house with faith or Christian Science, or that, with those agencies, you can remove a vermiform appendix.
>
> "Nobody should interfere with a faith healer or mental healer because that individual takes a dollar or $10,000 from the adult who wishes to employ him. So far as adults are concerned, there is no harm in allowing faith healers to treat their non-contagious diseases from stone-bruise to lockjaw. If the adult is willing to die of a non-contagious disease in order to demonstrate a theory, let him. Such an adult can be spared. But faith healers and others must not be permitted to deal with contagious diseases or pretend to cure them—that is dangerous to the public at large. . . .
>
> "It is not a fact that 100 years from now all doctors will cure with thought. One hundred years from now and 1,000,000 years from now matter will act on matter, and the agency used will be force directed by thought. Thought is the directing agency.
>
> "There are three things in the world—Thought, which rules and directs—Force, which carries out the orders and conceptions of thought—and Matter, in which thought realizes itself and its visions.
>
> "A hundred years from now and a million years from now the surgeon's knife will remove the tumor, if it still exists, just as the plow will cut through the soil and the hammer will carve the stone. But perhaps in a few hundred years, and certainly in a million years, increased intelligence among men, greater self-control, absolute sobriety, wise living, scientific knowledge, even among children, will make disease almost unknown, and limit the activities of physicians almost entirely to prophylaxis, which is prevention.
>
> "But even in a million years, and in ten million years, if the human race lasts as long as that, which it probably will, science, created by the mind, directing force and acting on matter will rule the world.
>
> "When you find a faith healer who can build a hen house with faith and without tools, or move a pebble half an ounce in weight without touching it, when you are willing to trust your plumbing to a faith plumber who says he can cure the leak by thinking about it, then trust your body and your internal plumbing to the medical plumber who cures with thought."

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

[Note.—The pamphlets containing the outline of the postgraduate study course for county societies for the coming year are now ready for distribution. Secretaries of county societies can secure supplies by writing to the Secretary, Council on Health and Public Instruction, American Medical Association, 535 Dearborn Ave., Chicago.]

First Month—First Weekly Meeting

General Subject for the Month: Tumors

Anatomy and Histology: Epithelial Tissue

ORIGIN, STRUCTURE, CELLS AND STROMA

Varieties: Simple and compound.

Shape, Arrangement and Distribution: (1) pavement, (2) cubical, (3) columnar, and (4) ciliated. Describe ciliary motion, causes.

Transitional Epithelium: Arrangement, distribution and location.

Stratified Epithelium: Shape, arrangement and distribution.

Nutrition of Epithelium: Chemistry of epithelium.

Connective Tissues

ORIGIN, STRUCTURE, FUNCTION

Areola: Distribution, structure, microscopic appearance, cells, matrix, white and yellow fibers.

Fibrous: Distribution, structure, functions.

Elastic: Structure, distribution, histology.

Adipose: Distribution, structure, function, nutrition.

Lymphoid and Retiform: Distribution, histology.

Jelly-like: Stricture, chemistry, distribution.

Cartilage: Varieties, structure, function, chemistry.

Bone: Chemistry: structure (gross and microscopic), nutrition.

Blood: Corpuscles (red and white), plasma, serum and fibrin.

Muscular Tissue

ORIGIN, VOLUNTARY AND INVOLUNTARY

Striated and Plain: Distribution of each.

Striated, Voluntary: Epimysium, perimysium, endomysium. Sarcolemma and contractile substance. Sarcomere, sarcostyle and contraction. Attachment to tendon. Nutrition of muscle. Nerve supply.

Plain, Involuntary: Distribution. Shape, size, arrangement of cells.

Cardiac Muscle: Differs from others.

Nervous Tissue

ORIGIN, CENTRAL AND PERIPHERAL SYSTEMS

Cells and Fibers: Distribution.

Fibers.—Medullated: Sheath, axis cylinder, neurilemma, nuclei, nodes of Ranvier.

Non-Medullated: Transverse and longitudinal sections.

Cell: The neuron, cell body, dendrites, axite.

Bipolar cells, distribution, function, description.

Multipolar cells, Golgi cells, two types.

Histology of the cell, staining, shape, size, etc.

Nerve degeneration and regeneration.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Iowa: Capitol Building, Des Moines, September 19-21. Sec., Dr. Guilford H. Sumner.

Massachusetts: State House, Boston, September 12-14. Sec. Dr. Edwin B. Harvey.

Missouri: Kansas City, September 25-27. Sec., Dr. Frank B. Hiller, Jefferson City.

New York: September 26-29. Mr. Harlan H. Horner, Chief of Examinations Division, Department of Education, Albany.

Virginia June Report

Dr. R. S. Martin, secretary of the Medical Examining Board of Virginia, reports the written examination held at Richmond, June 20-23, 1911. The number of subjects examined in was 9; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 117, of whom 93 passed, including 3 osteopaths, and 24 failed, including 2 osteopaths. Nine candidates were licensed through reciprocity. The following colleges were represented:

Book Notices

[illegible] ÖSARTIGEN NEUBILDUNGEN DER BAUCH- [illegible] hmidt, k. k. primarazt am k. k. Kaiserin [illegible] er. Price, 14 marks. Pp. 355. Vienna: (American Publishers: Rebman Co., New York), 1911.

The diagnosis of tumors of the abdomen has always been a matter of difficulty. The good results following operation on many such tumors, even malignant ones, make it incumbent on the physician to make as early and as accurate a diagnosis as possible. To one aiming to do this and conscious of the difficulties, Schmidt's book will be of peculiar help.

One good thing about this work is that the author sticks to his text. He talks of malignant growths and not of the non-malignant; there is little of etiology, pathology or treatment, except as it has a direct bearing on the question of diagnosis; there is no needless argument about things theoretical; there is almost nothing of the polemic. There are occasional lapses into unnecessary repetition, but conciseness is the rule.

The book is essentially clinical and based largely on the author's own experience. There is little of quotation or citing of authorities, though one cannot accuse Schmidt of being ignorant of what others have written, for there is clear evidence that he is well informed. Not only does he rely largely on clinical facts in order to reach a diagnosis, but he is inclined to believe that the study of cases of malignant growth from the clinical aspect may throw a great deal of light on the question of etiology. He questions whether the laboratory will detect the one specific cause. He sees the operation of so many contributing factors that he regards the development of a malignant growth as often depending, in part at least, on such facts as a previous freedom from infectious diseases, the existence of dyscrasic conditions producing cell trauma, even the influence of depressing psychic causes.

In line with his emphasis of the clinical features of these neoplasms is his relegation of what are commonly termed laboratory methods to a position of secondary importance. It is not to be understood that he overlooks the aid of the laboratory. Far from it. His directions as to laboratory technic and the value of such examinations are clear and detailed. Yet, the greater importance seems to attach to the history, the symptoms and the examination of the patient's body. The necessity of careful and repeated examinations of the stools for occult blood is referred to over and over again. Yet Schmidt issues a note of warning against the employment of tests that are too delicate and that might detect minute traces of blood which mean nothing in the way of disease. Such tests, he says, may be of chemical but not of clinical interest; they are of "decorative" rather than practical value (p. 97). The various functional tests of the kidney he regards as of slight reliability. He seems loath to employ even instrumental help; the *x*-ray must not be relied on too implicitly; it is rarely necessary to distend the stomach or bowel as an aid to diagnosis. Careful study of the history with attention to even the minutest symptoms, with thorough physical examination will make the laboratory and instrumental examinations not unnecessary but rather auxiliary or confirmatory. Is not this, after all, the right view? Two points in physical examination are often referred to, the one the help to be derived from palpation with the patient in the lateral decubitus, with which one must heartily agree. The other is the stress laid on the value of auscultation for murmurs in the diagnosis of tumors of the stomach, liver, gall-bladder, pancreas, etc. To us, this method seems not to warrant the overemphasis placed on it by Schmidt. The methods of the teacher are seen in a tendency to reduce diagnostic symptoms to tabular form. This is helpful, though at times the tables seem rather artificial and too refined. Take, for example, his subdivision of the pains of carcinoma of the stomach. Stripped of its classification, it means that carcinoma of the stomach may cause pain anywhere in the region of the body from the upper thorax to the symphysis pubis.

The portrayal of the features of typical cases is excellent, but the great value of the book lies in its discussion of atypical cases and its reference to possible misleading symptoms. The exceptional case is the one apt to confuse and is the one on which the author dwells particularly.

We should like a clearer differentiation between ulcer of the stomach and carcinoma. The author's statement that few cases of carcinoma of the stomach originate in ulcer will be questioned by many, though the relation between these two conditions is by no means definitely established. Cardiospasm as a misleading condition should be mentioned in discussing gastric cancer. Other minor features might be criticized, the criticism based largely on the fact that one's personal experience does not tally exactly with that of the author. But the book, as a whole, merits praise as a valuable contribution to the clinical study of malignant tumors of the abdomen.

The last half of the book is taken up with abstracts of cases. The abstracts are excellent. It was from a study of these cases with controlling operation or autopsy that the author was able to write the first half of the book. Numerous references to these cases are to be found throughout the work.

PRACTICAL CYSTOSCOPY AND THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEYS AND URINARY BLADDER. By Paul M. Pilcher, A.M., M.D., Consulting Surgeon to the Eastern Long Island Hospital. Cloth Price, $5.50 net. Pp. 398, with 233 illustrations. Philadelphia: W. B. Saunders Co., 1911.

This is an elaborate and admirably illustrated treatise, in which "the writer has endeavored to state fairly the indications for cystoscopy, and to outline its technic in the minutest detail, describing the instruments used and how to use them." This, the major content of the book, is commendable in conception and execution; it is obviously based on ample personal experience. There is apparent a tendency toward ill-considered statement, such as the possible differentiation by the cystoscope of a dozen varieties of cystitis; the virtual denial of all chance of extending infection by the ureter catheter if skilfully used; and the extravagant eulogy of a certain cystoscope.

Cystoscopy through a suprapubic puncture, occasionally a valuable procedure, seems worthy of mention in every complete treatise on methods for inspecting the bladder. The jumble of Latin and English in a prescription (p. 92), while a merely academic offense, illustrates the lack of care which is often apparent in the text.

The accessory portion of the work, which discusses collateral methods of diagnosis, is less acceptable; indeed, some of this matter is distinctly misleading. Such is the statement (p. 195) "the only way of definitely determining the character of the ulcer" (whether tuberculous or other) "is by finding tubercle bacilli in the urine or by a guinea-pig test." The marked hyperemia around a tuberculous ulcer, which follows a subcutaneous injection of tuberculin, more quickly and surely distinguishes it from other ulcers than does either of the "only" tests recommended.

The book is probably the most complete exposition of cystoscopy in our language, and will repay perusal by any one who uses the cystoscope.

A TEXT-BOOK OF VETERINARY ANATOMY. By Septimus Sisson, S.B., Professor of Comparative Anatomy in Ohio State University, Columbus, Ohio. Cloth. Price, $7 net. Pp. 826, with 528 illustrations. Philadelphia: W. B. Saunders Co., 1910.

This book, of nearly 850 pages, is an evidence of the fact that the study of the anatomy of domestic animals and the making of books thereon is keeping pace with similar work in human anatomy. The author says that this book has been made in response to a demand for a well-illustrated and up-to-date book on veterinary anatomy, and a cursory review would seem to indicate that the purpose has been well fulfilled. The descriptions are clear, full and scientific. The comparative anatomy of the various domestic animals is always kept in view, which adds value to the work. The nomenclature adopted is that of the best authorities in this and foreign countries. The work should rank well with the books on human anatomy and should meet every requirement of the veterinary student. Mechanically, the book is very satisfactory.

Text-Book of Operative Surgery. By Dr. Theodor Kocher, Professor of Surgery and Director of Surgical Clinic in the University of Bern. Third English Edition. Authorized Translation from the Fifth German Edition by Harold J. Stiles, M.B., F.R.C.S., Edin., Surgeon to the Chalmers Hospital, Edinburgh, and C. Balfour Paul, M.B., F.R.C.S., Edin., Assistant Surgeon, Royal Edinburgh Hospital for Sick Children. In Two Volumes. Cloth. Price, $12 net. Pp. 723, with 415 illustrations. New York: The Macmillan Co., 1911.

Kocher's "Operative Surgery" has been before the profession for several years and is well known by all who practice surgery. This is the third English edition translated from the fifth or last German edition. The translation has been very well done; one seldom sees a translation from the German that reads as smoothly as does this.

In reading the author's preface one cannot help being charmed by his great earnestness and by his endeavor to impress on all who essay to do surgery the great responsibilities which rest on them. These delightful features are stamped on every page of the work for the author does not simply describe typical and classic procedures but he deals with conditions and each operation is given that touch of life which marks the author as a master and a great teacher. One short quotation under "Surgery of the Gall-Bladder and Bile-Ducts" will suffice to illustrate what is meant:

"Surgeons should realize that it is their duty to the patient to pull him through his illness and not to perform an operation that is classic. This object cannot be obtained by any routine operation, whether based on old or on the most modern theories. Operations which are theoretically excellent when put in practice may often cause the death of the patient because his individual needs are not taken into consideration."

It is this attempt of the author to individualize, coupled with his great experience, which gives to this work its great value.

The only criticisms to be made are those relating to the publisher. The work appears in two volumes instead of one—as in the original German edition—although there are but 723 pages all told, including the index. To give the volumes the appearance of size unusually thick and heavy paper is used. Many large illustrations are unnecessarily duplicated, some of them as often as four times, etc. These defects should be corrected.

It might also be well, in view of the prominence of the translator, to give him the recognition to which he is entitled by placing his name on the back of the volumes below that of the author.

Kursus der normalen Histologie Ein Leitfaden für den praktischen Unterricht in der Histologie und mikroskopischen Anatomie. Von Rudolf Krause, a.o Professor der Anatomie an der Universität Berlin. Paper. Price, 22 50 marks. Pp. 441. Berlin: Urban & Schwarzenberg (New York: Rebman Company), 1911.

The special object of Professor Krause's book is to promote the practical instruction of students in histology and microscopic anatomy. The plan is that the student himself shall prepare most of the preparations described. For this purpose the freezing method is used as well as the paraffin and celloidin methods. Particular emphasis is placed on the value of drawings in the study of the microscopic preparations and all the illustrations—about 208, reproduced by autotype—have been drawn in colors by the author himself. We fear that only few of the students ever reach the standard he has established. The book is divided into two general parts; the first deals with technical matters; the second takes up the cell, the tissues and the organs of the animal body. The text of this part is in reality a plain and succinct explanation of the illustrations together with statements as to the technical methods employed in preparing the objects illustrated. Most of the preparations are of human origin. The illustrations are really very fine. While it is quite obvious that the book has been prepared with direct reference to German conditions, it undoubtedly will prove to be a highly useful book anywhere. It is recommended heartily to the consideration of American teachers of normal histology in the hope that it may prove of assistance in imparting to their students a working knowledge of the microscopic structure of the body and of microscopic technic, heretofore as a rule but indifferently accomplished if we are to believe the testimony of the teachers of pathological anatomy and of clinical laboratory work.

The Fats. By J. B. Leathes, M.A., M.B., F.R.C.S., Professor of Pathologic Chemistry in the University of Toronto. Cloth. Price, $1.25 net. Pp. 138. New York: Longmans, Green & Co., 1910.

Although not all the promised monographs of this series have yet appeared, already one of the earlier ones has come to a second edition. This is satisfying evidence that the value of these publications is being recognized. So rapidly changing is the subject-matter of biochemistry that no other form of publication can well be so efficient as the one adopted here; namely, inexpensive monographs written by specialists, each covering that part of the entire field with which each writer is most intimately acquainted.

"The Nature of Enzyme Action," the first of the series to enter a second edition, covers adequately and accurately this interesting and fundamentally important subject. Presented originally in the form of lectures, it is more easy to read and assimilate than treatises of this sort are likely to be, a point of particular favor in the eyes of readers who are interested in the subject only in its general aspects. In the new edition the more recent contributions to enzyme chemistry and the theories of enzyme action have been incorporated, the author assuming the reasonably conservative attitude necessary in considering a subject in which theorization is so prominent.

The monograph on fats, by Professor Leathes of Toronto will particularly interest scientific physicians because of the rapid increase of our knowledge of the importance of fats and related substances in biologic processes. Until recently looked on as merely stored food material, the fats and lipoids have now been revealed as vitally concerned in cell activities, almost if not quite as much so as the proteins themselves. They enter, not only into normal processes, but also into the phenomena of immunity, and they modify or determine the effects of many of our most important drugs. With admirable conciseness, but without impairment of reliability, Professor Leathes presents the latest reliable information concerning the chemical composition and behavior of the fats and "lipines" (as he prefers to call the compounds of fatty acids which contain nitrogen), their physical properties, methods of analysis, and the part played in physiology. From our point of view we should have preferred more on the physiologic aspects, concerning which the author himself has made most interesting and inspiring contributions, but as the physiologic side is at present much more speculative than the chemical, the concession of most of the space to the established matter is perhaps the part of wisdom. In any case, the scientific physician will find in this monograph as much to interest and enlighten as in any member of this valuable series.

Die Hodgkinsche Krankheit. Von Dr. Kurt Ziegler, Privatdozent in Breslau. Paper. Price, 9 marks. Pp. 204, with illustrations. Vienna: Gustav Fischer, 1911.

This book is an exhaustive treatise on the subject of Hodgkin's disease. The literature is reviewed fully and the author gives his own observations based on a study of seventy cases, in sixteen of which autopsies were held, and in forty cases microscopical examinations of diseased glands were made. In accordance with the present tendency he considers the disease as a specific inflammatory process. The histology is especially well illustrated in five plates with twenty-two beautiful colored pictures. The completeness of the work is well shown in the 600 literary references at the end of the volume. This extensive monograph will take a foremost rank among the treatises on this strange disease.

Psychiatrische Vorträge für Aerzte, Erzieher und Eltern. (Zweite Serie). Von Prof. Dr. G. Anton, Direktor der Klinik für Geistes- und Nervenkranke in Halle a. S. Paper. Price, 2 marks. Pp. 77. Berlin: S. Karger, 1911.

This series of popular lectures on psychiatric themes was prepared for physicians, educators and parents. They constitute good reading and appear under the following titles: "1. The Expression of the Emotions in Healthy and Diseased Persons." "2. Mental Epidemics of Past and Present." "3. Normal and Abnormal Development of the Child." "4. Alcoholism and Heredity." "5. The Causation and the Operative Treatment of Epilepsy." These lectures are written in popular style and can be safely put into the hands of any educated person.

Denial of Sexual Intercourse as Ground for Divorce, Especially When a Matter of Health

(*Raymond vs. Raymond* (*N. J. Ch.*), *79 Atl. R. 430; Lohmuller vs. Lohmuller* (*Tex. Civ. App.*), *135 S. W. R. 751.*)

The Court of Chancery of New Jersey holds that a spouse's wilful refusal to engage in sexual intercourse is desertion under the statute, making desertion a ground for divorce, and, hence, where a husband refused to consummate the marriage by sexual intercourse, he deserted his wife, even though he supported her, and they lived under the same roof. It says that the cases generally admit that unjustifiable withdrawal from marital cohabitation constitutes desertion. Marital cohabitation implies necessarily something more than merely living under the same roof. Where will the line be logically drawn, unless it is held that to constitute matrimonial cohabitation it must include those duties which distinguish the marital from every other contractural relation? When cohabitation in its true sense in the marriage relation ceases, desertion commences.

But the Court of Civil Appeals of Texas holds that a decree of divorce was wrongly granted where the testimony of the plaintiff showed that the sole ground for the divorce was a refusal on the part of his wife to sacrifice herself to his sensual desires, the uncontradicted evidence showing that she was a nervous, frail woman, who would probably die if she bore another child, and the plaintiff was fully advised of that fact by the family physician, and he was also told that he should not demand that his wife submit to his embraces, except under certain conditions, which conditions the plaintiff stated rendered him nervous and made him sick, but which the only physician who testified stated could not and did not injure him; in fact, could have no hurtful effect whatever. The refusal to accede to the passion of a man who knew that childbearing would destroy the life of his delicate, nervous wife, and who was unwilling to inconvenience himself in any way to prevent such a catastrophe, would not constitute such "excesses, cruel treatment, or outrages" toward him as would entitle him to a dissolution of the marriage ties. Even an unjustifiable refusal of marital rights is not necessarily a cause for divorce, and when there is no refusal but merely certain conditions are prescribed which cannot injure the husband, but will protect the wife from probable death, the divorce should not be granted.

Railroad Companies Not Liable for Malpractice in Hospital Departments—Office of Physicians

(*Arkansas Midland Railroad Co. vs. Pearson* (*Ark.*), *135 S. W. R. 917.*)

The Supreme Court of Arkansas had in this case for decision for the first time for that state the question of the liability for malpractice of a railroad company maintaining a hospital department out of funds deducted from the wages of employees. Its conclusion is that the law was correctly stated in an instruction given to the jury that, even though the hospital at St. Louis and the local surgeons at different points on the railway system of the company, were maintained by small sums of money deducted monthly from the wages of the employees of the company, yet the only duty which it owed its employees in regard to medical and surgical attention was to use reasonable care in the selection of physicians, surgeons or attendants.

It is generally held, the court says, that hospitals conducted for charity are not responsible for the negligence or malpractice of their physicians, and that persons and hospitals which treat patients for hire, with the expectation and hope of securing therefrom gain and profit, are liable for such negligence and malpractice on their part.

This hospital department could not be said to be conducted as a charity, for only those employees who had contributed the fees deducted from their wages for its maintenance were entitled to enter there for treatment, and all the physicians and employees required to maintain and operate it were paid from such fund. Nor could it be said to have been administered by the railroad company out of pure philanthropy, since it may have had some benefit therefrom in decrease of amount of damages for injuries caused in the operation of the road, and the better and more efficient service to the company of its employees because of its maintenance. It was also true that none of the employees was required to accept the treatment provided at the hospital, and none could do so unless before their service with the railroad company was ended, thus in effect creating a fund for the benefit of themselves, it might be, and certainly for others.

It was not contemplated by the employees in their contribution to this fund that it should be used in the payment of damages for the negligence or malpractice of physicians employed in the operation of the hospital department, and certainly the railroad company that assumed gratuitously to collect and preserve the fund and provide hospital accommodations and competent physicians and surgeons to operate it, without any profit or gain or hope thereof therefrom, should not be required to pay damages for such negligence or malpractice; it being no part of its business under its charter to maintain a hospital. At most it could be considered only a trustee for the proper administration and expenditure of the fund, and should be held only to ordinary care in the selection of competent and skilful physicians to administer relief and provide attention to sick and injured employees. If the railroad company did in fact realize a profit from the total deductions from the wages of its employees for the hospital fund, after paying for the support and maintenance thereof and the employment of physicians, or if it agreed and contracted with such employees in consideration of the fees paid by them to furnish proper medical attention, the rule might be different.

A physician cannot be regarded as an agent or servant in the usual sense of the term, since he is not and necessarily cannot be directed in the diagnosing of diseases and injuries and prescribing treatment therefor; his office being to exercise his best skill and judgment in such matters, without control from those by whom he is called or his fees are paid.

Powers Conferred by Statute on Board of Health—Unwarranted Regulation of Sale of Milk

(*Commonwealth vs. Drew* (*Mass.*), *94 N. E. R. 682.*)

The Supreme Judicial Court of Massachusetts says that this was a complaint against the defendant for violation of a regulation of the board of health of the city of Boston which provided that: "No person or corporation shall sell or offer, expose or keep for sale in any shop, store or other place where goods and merchandise are sold, milk or cream, unless the same is sold or offered, exposed or kept for sale in tightly closed or capped bottles or receptacles which have been approved by the board of health." The court does not consider the question whether this regulation went beyond the constitutional power of the legislature to enact as a statute, or to authorize the board of health to establish locally, but simply holds that the statute under which the board assumed to act was not broad enough to give authority for it. That statute was as follows: "The board of health shall examine into all nuisances, sources of filth and causes of sickness within its town, or on board of vessels within the harbor of such town, which may in its opinion be injurious to the public health; shall destroy, remove or prevent the same, as the case may require, and shall make regulations for the public health and safety relative thereto and relative to articles which are capable of containing or conveying infection or contagion, or of creating sickness, which are brought into or conveyed from its town, or into or from any vessel."

That statute does not give the board power to make regulations as to all matters affecting the public health. If the board should be certain that the smoking of cigarettes by boys affects their health injuriously, it would have no power to make a regulation forbidding the smoking of them by boys under a certain age, or the sale of them to such boys. It has no power to make general regulations as to conduct or practices injurious to health, which, if indulged in by many persons, affect the health of the public.

The statute gives the board jurisdiction to deal with "nuisances, sources of filth and causes of sickness within its town." It was agreed that the milk kept for sale by the defendant was kept in a vessel contained in a covered cooler; that it was always kept at a temperature less than 50 degrees Fahrenheit, and that none of it was allowed to stand outside of the cooler except while a sale of milk was being made; that the cooler was always kept properly drained and cared for and tightly closed, except during such interval as was necessary for the introduction or removal of milk or ice, and was kept in such location and under such conditions as were approved by the board of health. The milk was wholesome milk of standard quality, was taken from a clean, new tin cylinder or vessel, set in a clean, new ice chest, surrounded by clean, wholesome ice. The vessel had a removable cover which was new and clean, and the measure which was used by the defendant in retailing the milk was new and clean, and hung inside the tin cylinder so that it was not exposed to the air. The cylinder was simple in shape, was easily cleaned and was susceptible of perfect sterilization. The sales were made in any quantities desired by customers from one cent's worth upward. Plainly the milk in question was not a nuisance or a source of filth.

In determining the meaning of the words "causes of sickness," the doctrine of *noscitur a sociis*, or the meaning of a word is or may be known from the accompanying words, was to be applied. Primarily it referred to something local, and the board was directed "to destroy, remove, or prevent the same."

The court is further of the opinion that, within the meaning of the language of the statute, milk kept in a vessel, as this was kept by the defendant, was not a "nuisance, source of filth, or cause of sickness," which gave the board of health jurisdiction to take any action or make any regulation under the portion of the statute which gives the board jurisdiction to make regulations "relative to articles which are capable of containing or conveying infection or contagion, or of creating sickness, which are brought into or conveyed from its town, or into or from any vessel." That has reference to the bringing into the town or conveying away of articles capable of containing or conveying infection, in such a way as to affect injuriously the public health or safety. It relates to articles of such a kind as to be dangerous in reference to their capability of containing or conveying infection or contagion, or of creating sickness, in connection with their removal from one town to another. Pure milk is not such an article as is referred to in the statute.

Another Court Holds Chiropractic a Practice of Medicine—Sufficiency of Complaint and Validity of Law—"Adjustments" are "Treatments"

(*State vs. Greiner (Wash.), 114 Pac. R. 897.*)

The Supreme Court of Washington affirms a conviction of the defendant who was charged with practicing a mode of treatment of the sick and afflicted known as chiropractic, without having at the time of so doing a valid, unrevoked certificate to practice such mode of treatment from the proper authorities. The court says that the Code makes it a misdemeanor for any person to practice, or attempt to practice, or hold himself out as practicing, medicine and surgery, osteopathy or any other system or mode of treating the sick or afflicted in the state of Washington, without having at the time of so doing a valid, unrevoked certificate from the Board of Medical Examiners of the state, entitling him so to do. The complaint, while not to be recommended as a model, charged in effect that the defendant, at a time and place certain, did wilfully and unlawfully practice a mode of treatment of the sick known as chiropractic, without having a license therefor from the proper authorities, in that she did then and there prescribe, direct and recommend certain treatment for the cure and relief of certain bodily infirmities and diseases of the complaining witness. That was sufficient. It was not necessary, under the Washington Code, that the acts constituting the offense be set forth in the complaint with the technical precision required at common law.

It was a material fact in the case that the defendant used a vibrator on the prosecuting witness.

The evidence, it was argued, was insufficient to justify a conviction. The statute, it will be noticed, makes it an offense to practice any mode of "treating" the sick and afflicted, and the defendant testified that, instead of using treatments for the ailments of the prosecuting witness, she used "adjustments," and hence was not guilty of any violation of the statute. But the court thinks that was a mere play on words. Her methods were fully described in the record, both by the prosecuting witness and by herself, and to the mind of the court they fell as well within the definition of "treatment," as they did of "adjustment." She had the patient remove her street clothing and put on a kimono; she diagnosed the patient's ailments with the aid of a vibrator; she manually manipulated the supposedly diseased parts; she prescribed a dietary for the patient; she collected a fee, and advised the patient to return for further manipulation. That, so far as the court's observation extends, did not differ materially from the methods of unlicensed practitioners generally, who confessedly give treatments for the sick and afflicted.

It was finally objected that the act under which the defendant was prosecuted was unconstitutional. It was objected, first, that it embraced more than one subject, and, second. that the science practiced by the defendant was not a subject for regulation by the legislature. Neither of these objections was well founded. The purpose of the act is to regulate the mode of treating the sick and afflicted, and the fact that it may contain provisions affecting a variety of practitioners, having different systems and methods of treating the sick, does not render it subject to the objection that it contains more than one subject. The science, if it be such, practiced by the defendant is clearly a mode of treating the sick and afflicted. As such it is by all authority subject to regulation. To call the method of treatment "chiropractic" and the treatments given "adjustments" does not change its nature. If the practice has any beneficial purpose at all, its purpose is to heal the sick and afflicted, and to regulate the practice of healing the sick and afflicted is unquestionably within the acknowledged powers of the state.

1. Peritonization in Pelvic Surgery.—The procedure to which Summers refers particularly and one with which he has had many personal experiences, consists in transporting the sigmoid flexure across the pelvis and suturing it in such a way that all raw surfaces are covered over. The sigmoid is only fixed below and is almost always sufficiently mobile to be carried across the pelvis to the right side as far as the cecum. When the uterus is preserved the sigmoid is sutured to the lateral walls of the excavation and across the fundus of the uterus. When the uterus is sacrificed the sigmoid is sutured to the lateral walls of the excavation and to the bladder. Drainage should be made through the vagina. Except in cases of total hysterectomy, Summers has almost always employed a cigarette drain coming out of the extraperitoneally excluded space between two of the stitches, tacking the sigmoid flexure in position and draining externally at the lower angle of the abdominal incision. The fastening of the sigmoid as indicated has never, in a large number of cases in which Summers has used the method, interfered in any way with the function of the bowel. This technic is said to be particularly advantageous when septic pus or genital abscesses communicate with the intestine; for example, a pyosalpinx, or suppurating tumor of the ovary, opening into the large bowel; again, when there coexist a genital abscess with a perforative appendicitis. The intestinal sutures are situated under the protection of the cavity drained and are extraperitoneal.

2, 3 and 7. Abstracted in THE JOURNAL, July 29, 1911, pp. 414 and 415.

4. **Salt Solution as Filling for Bone Cavities.**—Some years ago, in doing an operation for the removal of the Gasserian ganglion, Sherman wounded the dura mater and had to suffer, during the operation, from the annoying leakage of cerebrospinal fluid. When it came time to close the wound the squeezed-up brain in the collapsed sac of the dura mater did not readily expand to fill the space within the skull. In order to avoid leaving a large amount of air in the wound, Sherman poured in sterile physiologic salt solution, and sutured the scalp over it. The wound healed normally and the patient recovered uneventfully. Since then he has used salt solution to fill all cavities or spaces that could not be closed by suture, except that he has not used it in cavities or spaces that were actually or potentially septic.

In four instances children presenting themselves with the symptoms and signs of hip-joint tuberculosis were shown, by radiogram, to have localized tuberculosis foci or abscesses in the diaphysial portion of the femoral neck. In these instances Sherman has opened the trochanter by a trephine, extended the wound to the abscess, cleaned it out and removed the softened bone around it, and then filled the cavity with physiologic salt solution and sutured the fascia and integument over the bone wound. In one instance there occurred normal healing which was permanent, the tuberculous process stopped and the child made a relatively quick and complete recovery, which has been permanent for four years. In two instances there occurred normal healing, but the tuberculosis was not controlled and the cases followed the usual course of a hip-joint tuberculosis, not benefited by the operation. In the fourth instance there occurred normal healing and the child returned home in a plaster-of-Paris spica. Within a month after the operation an acute pneumonia developed and caused death. Sherman secured the head, neck and trochanter on which he had operated. The wound cavity he had made in the trochanter and neck was filled by a layer of granulation tissues with a blood clot, apparently undergoing absorption, in the center. Four other cases are cited.

The method is, in reality, a reversion to Schede's filling, but with an improved technic, *in that the wound is not closed* before the removal of the Esmarch tourniquet, nor is a drainage arranged for. Instead of this, hemostasis is secured in the usual way, then the bone wound is *filled with* the salt solution and the soft tissues are sutured closely with no drainage. In all instances so far healing has been normal and permanent.

5. **Normal Human Blood-Serum to Prevent Postoperative Hemorrhage.**—This procedure, first used by J. E. Welch as a curative agent in hemophilia neonatorum, has been resorted to by Meyer in four cases with good results. The jaundice in all of the four cases reported was due to carcinoma. In none did any parenchymatous hemorrhage occur after the prophylactic and postoperatively resumed injections of normal human blood-serum. The favorable outcome in the first case was remarkable: after the preliminary injection of a total of 105 c.c. (3½ ounces) of normal human blood-serum, no more being on hand, and 30 c.c. directly after the operation, a severe intestinal hemorrhage sets in ninety hours after operation; patient's condition desperate. Under resumed serum treatment the fever soon drops, bleeding ceases permanently, and patient recovers. Meyer says that the injections should be started at least two days before operation, 30 to 60 c.c. (1 to 2 ounces) to be administered three times per day, and should be continued right after operation for another forty-eight to seventy-two hours. It is wise to provide for the serum in time; both cephalics of two healthy individuals should be tapped; they will yield from 300 to 400 c.c. (10 to 14 ounces) of serum. Wassermann's reaction should, of course, be made; it does not seem of great importance, according to Meyer's observations, to test and follow up the coagulation time of the blood, although the latter appeared repeatedly reduced in course of the serum treatment.

10. **Uninterrupted Anesthesia in Operations on Face and Mouth.**—Souchon has devised a small apparatus for the purpose of keeping up the anesthesia uninterruptedly by introducing a rubber tube into the throat through the nose and mouth.

11. **Nitrous-Oxid Anesthesia.**—On the theory that nitrous oxid owes its anesthetic property to its power of limiting oxidation in the brain tissue, and the theory that shock is due to an exhausting activity of the brain cells due to injury, Crile says one might very properly infer that the brain cells were by nitrous oxid prevented from making the harmful expenditure of energy, thus minimizing the shock. The exclusion of fear and of trauma from the brain prevents any nocuous associations. This state is expressed by Crile by coining a new word, viz., anoci-association. Operations on neurasthenic subjects under anoci-association preserves to a remarkable degree the nervous system.

12. **Treatment of Inoperable Sarcoma.**—Up to the present time Coley has had sixty-five cases of inoperable sarcoma in which the tumors disappeared under the use of mixed toxins of erysipelas and bacillus prodigiosus. The utmost efforts have been made to trace the after-histories of these cases, with the following results: Seven remained alive and well at the end of fifteen to eighteen years. Seven remained alive and well at the end of ten to fifteen years. Seventeen remained alive and well at the end of five to ten years. Ten remained alive and well at the end of three to five years. That is, forty-one cases remained well from three to eighteen years, or thirty-one from five to seventeen years. As to the correctness of the diagnosis in these cases, Coley says that they were practically selected cases, i. e., selected by the leading surgeons of America, as hopeless, inoperable cases. In all of these cases, with exception of four, the diagnosis was confirmed by careful microscopic examination, in most cases not by one, but by several of the most competent pathologists. In order to still further eliminate all chance of error in diagnosis in a large number of the cases, there was a history of very rapid growth and repeated recurrence after operation. If further evidence were needed, it is furnished by a small number of cases in which, after the complete disappearance of the tumor under the toxin treatment, the disease afterward recurred locally and generally and caused the death of the patient.

13. **Intestinal Perforation in Typhoid.**—Bagley presents the results of a statistical study of all cases of intestinal perforation in typhoid recorded in the literature from 1884 to the present.

17. **Intestinal Anastomosis by Invagination.**—By *invagination* Grant *means a complete invagination of one gut bodily into another, the lower end of the upper segment, preferably 2 or more inches.* He reports one case of obstruction in the sigmoid due to a small tumor in which he employed the method successfully. A long, curved, strong-bladed forceps was inserted through anus and rectal segment, and the latter being very much constricted at inner, or upper, end was

stretched by spreading the blades of the forceps. The upper, or sigmoid segment, was grasped by the forceps and pulled through rectum and anus, making a snug fit at the upper rectal opening. The peritoneal cavity was now flushed with warm salt solution. Two or three interrupted stitches were applied to the invaginated gut and lower posterior uterine surface, the latter being the only fairly normal tissue in the vicinity. The patient was now put in lithotomy position, and the sphincter ani divided subcutaneously, in order to facilitate drainage. The invaginated gut was fixed with four silkworm-gut sutures to the mucocutaneous margin; and as an additional precaution against retraction and premature cutting through of the sutures, a safety pin was passed through a segment of the gut. For drainage, a rubber tube was inserted between the rectal mucosa and invaginated segment, and another through the invaginated or upper segment. By this means, drainage of both the pelvic peritoneal cavity and intestines was provided for. The abdominal wound was closed without drainage and patient put to bed in the Fowler position.

18. **Vaginal Shortening of Utero-Sacral Ligaments.**—This operation consists in exposing the utero-sacral ligaments at their insertion into the uterus, in cutting them off at the uterus, and in bringing them round in front of and below the cervix, and at the same time shortening them as may be found necessary, so that they become again a support to that part of the uterus. The operation is said to be indicated in cases of prolapse of the uterus due to or associated with elongation of these ligaments. Jellett says that if there is prolapse of the uterus alone, unaccompanied by prolapse of the vagina, then shortening of these ligaments followed by any operation for the cure of backward displacement, e. g., ventral suspension or Alexander's operation, is usually sufficient. If the perineum is torn, its repair and the suture of the levator ani muscles are also necessary. If the vagina is everted, and particularly if there is a large cystocele, Wertheim's interposition operation also is indicated, provided the patient is past the child-bearing period, or, if not, that the tubes are divided at the same time. If the patient is still likely to have children, an ordinary anterior colporrhaphy is safer. If the cervix is markedly hypertrophied in the supravaginal portion, then supravaginal amputation is also necessary. In a typical case of complete prolapse, with eversion of the vagina, hypertrophy of the cervix, and tearing of the perineum, Jellett usually performs an operation consisting of the following steps: 1. Curetting. 2. Supravaginal amputation of the cervix. 3. Shortening of the uterosacral ligaments by the vaginal route. 4. Interposition of the uterus (Wertheim's operation). 5. Colopoperineorrhapy.

19. **Local Uses of Formalin.**—Stewart has found that the 40 per cent. solution of formaldehyd is useful locally in infected wounds as a germicide. It should be used freely, left approximately one minute and then neutralized by abundant solution of hydrogen peroxid. In ulcerative offensive cancers its use checks discharge and odor with little pain. The fungus of sarcoma can be controlled very perfectly by this agent without bad results.

23. Abstracted in THE JOURNAL, July 29, 1911, p. 417.

24. **Pachymeningitis Interna.**—Blackburn is convinced that the essential feature of the condition is the primary formation of a fibrinous exudation on the inner surface of the dura mater as the result of some form of irritation, and that at the same time the dural surface is to a great extent denuded of its endothelium, which permits of the emigration of leukocytes and proliferated connective tissue cells into the meshes of the fibrinous layer. These cells then begin to show formative activity, fibroblasts are formed which by their growth and fibrillation form a loose connective tissue from which the fibrinous matrix gradually disappears. The new tissue becomes vascular by the formation of wide, thin-walled capillaries which grow into it from the pre-existing vessels of the dura, the process being exactly similar to the so-called organization of inflammatory exudates elsewhere. At first the new membrane may show no hemorrhage and not even pigmentation; it is thin, soft, nearly transparent, and only slightly rose-tinted, by the presence of new capillary vessels; but the thin-walled vessels being under slight abnormal tension due to the congestive hyperemia of the dura, are easily ruptured, and hemorrhage occurs within the membrane or between it and the dura. The effused blood if small in quantity is absorbed in time, leaving pigment behind as a rust-colored stain in the new membrane. Such new membranes may be formed, layer after layer, if the process continues, the newer membranes being formed on the inner surface of the older ones, and subsequent hemorrhages will occur between the lamina as they did primarily between the first-formed layer and the dura.

The organic connections between the new membrane and the dura are at first slight, being only by means of the vascular extension, so that when rupture of a vessel occurs the blood forces its way between the layers, new vessels are torn, and in this way the larger hemorrhages occur, frequently only limited by the margin of the area where the organic adhesions are firmer. Though hemorrhage is almost the rule in these neo-membranes, it is by no means always a prominent feature. Quite frequently in the newest films they are absent, and in some old and well-organized fibrous membranes blood extravasation shows no evidence of ever being prominent. Such neo-membranes from their organization, their firm fibrous character, and their perfect organic junction with the dura may be overlooked, or, if discovered, may be taken by the inexperienced for the inner layer of the dura.

33. **Unusual Monstrosity.**—In the case cited by Torbert labor started by a high rupture of the membranes. Palpation of the abdomen at this time was most interesting; the uterus was pulled well over to her left side and felt like a bicornuate uterus. In the left cornua was felt a soft solid tumor similar to a breech, but of a firmer consistency; the small parts were on her right and one fetal heart was heard. A head well engaged in the pelvis was felt from above and another breech was palpated on her right side. Labor was short, but the uterine contractions were frequent and severe, and at times the retraction of the median scar looked as if the uterus was about to rupture. After full dilation an easy low forceps operation was done under ether anesthesia and a male baby weighing 4 pounds delivered; the baby cried at birth. In a few minutes the feet of a second baby appeared in the vagina; these feet were clubbed and a monstrosity was then suspected.

Traction on the feet resulted in their coming off. Intrauterine examination disclosed the true condition; the smooth rounded upper pole of the monstrosity prevented any grasp of it. No fissures of the body could be felt in which to insert an instrument. Finally, after repeated efforts, the cranioclast was attached to one thigh extending up on to the abdomen; to the other thigh were attached two French hooks, and with suprapubic pressure and traction from below the monstrosity was delivered. The monstrosity weighed 3 pounds. There was one placenta, two cords and two amnions. The first twin had a temperature of 106 F., and died twelve hours after delivery; there was no autopsy.

The dissection of the monstrosity was interesting, showing an abnormal development of the genito-urinary tract with a deficiency of development of all of the other abdominal organs. The penis is an excellent example of congenital paraphimosis. Both feet were clubbed to a marked degree. On opening the monstrosity in the median line, the subcutaneous tissue was thick and edematous; several cyst-like cavities filled the tissues outside of the chest wall. In the chest cavity no lungs could be demonstrated, no heart was visible, but some tissue was run through, which proved to be cardiac in origin. No spleen, liver or pancreas were found. The intestines were rudimentary. The striking feature was the extraordinary development of the entire genito-urinary apparatus. The kidneys were large, the ureters patent, the testicles in the vicinity of the kidneys. The bladder and urethra were dissected out intact. The vertebral column stopped above at the dorsal region; section of the cord showed nothing abnormal on macroscopic inspection.

Sections were cut of pieces removed from the abdominal cavity, but no organs could be definitely determined, the probability being that the tissue was in the early embryologic form and so not recognizable.

47. **Anaphylaxis.**—The author was the patient in this case. While treating a virulent case of diphtheria in May, he took 500 units of diphtheria antitoxin. Beyond a slight urticaria, localized at the point of injection, there was no result. In December of the same year, he had three cases of diphtheria in the same family. While injecting one of the patients, a young boy, 5 years old, he struggled and the needle escaping from the skin of the lad, penetrated Kaufman's left thumb. He went to a drug store and injected himself with 1,000 units of diphtheria antitoxin. Inside of fifteen minutes the whole left arm was swelling until in a few hours it was about three times the normal size. There was intense pain in the member, with generalized aching, more or less nausea, and intense urticaria. There was no reaction at the site of injection suggesting infection, and, indeed, strict aseptic technic had been observed. The swelling gradually increased so that the fingers could not be closed. A blood count at that time showed 7,000 white cells with nothing abnormal, no rise of temperature and no symptoms of infection. He was given atropin sulphate, 1/150 grain, every four hours, until its full physiologic effect was apparent, ordered to bed and put on a restricted diet. The only comfort obtainable was by holding the arm in a vertical position. After four more days the swelling gradually subsided and has left no obvious effect.

56. ***Control of Hemorrhage from Inoperable Neoplasms of Bladder.***—Bangs states that one can relieve the hemorrhage from tumors of the bladder, which are a cause of great apprehension to the patient, by the use of a solution of creolin injected into the bladder. Creolin is an antiseptic with hemostatic properties. The author gives the histories of four cases in which it was used with benefit. A 1 per cent. solution is found to be efficient for this purpose. It relieves irritability of the bladder at the same time that it reduces the loss of blood, and in some cases it reduces the size of the tumor. Although there is no permanent cure to be hoped for by the use of the creolin treatment, still the life of the patient is made more comfortable and often prolonged considerably.

57. **Paralysis of Upper Extremity.**—Jacobson presents the histories of several cases of nerve injuries of the upper extremity with remarks on the diagnosis and treatment. The most frequent cause of partial paralysis of the upper extremity is injury of the musculospiral nerve; this occurs especially in fractures of the humerus, the nerve being torn at the time of the accident, or becoming compressed or adherent to the callus in the process of repair. The nerve can also be injured at a lower point, in the lower third of the arm in fractures. The injury is not always recognized at the time of the fracture, but appears when the splints are removed, with the characteristic wrist-drop and inability to extend the fingers. In two of the cases presented the nerve was adherent to the callus and separation of the nerve from the cicatrix brought about entire recovery. When there are visible changes in the nerve as a result of injury, recovery is slow. A case of fracture of the neck of the scapula with displacement of the head of the bone and adhesions to the brachial plexus caused complete paralysis of sensation and motion. No apparent injury of the nerve occurred, and a few days after operation motion began to return and recovery ensued. When there is complete division of the nerve trunk we have a different condition entirely. In such a case after uniting the nerve-ends six months after the injury good results were obtained; sensation was completely restored, and many muscular movements have returned. If a nerve is reunited soon after injury the immediate results are not better than after remote operation. If suppuration has occurred in the wound with granulation one will not get restoration of function without operation.

59. Early Diagnosis of Gastric Cancer.—Austin states that when patients are operated on before there is extensive stasis it is found that free hydrochloric acid is present in many cases. Positive hemolysis was found in twenty-two out of twenty-six cases of gastric cancer, while it was present but once in sixty non-carcinomatous cases of gastric trouble. When pepsin is found in marked amounts in the urine and there is little or none in gastric contents this points to gastric cancer. The presence of tryptophan in gastric contents is an indication of gastric cancer. The bromin test of stomach contents will give a violet color in the presence of tryptophan. In a series of cases tested by the author this test was negative in twenty cases out of twenty-two, and one of these showed a palpable tumor. The tryptophan test is considered by the author the most available test for cancer that can be used in a clinic.

60. Russo's Typhoid Test.—Russo's test for typhoid is performed as follows: To 4 or 5 c.c. of the patient's urine add 4 drops of a 0.1 per cent. aqueous solution of methylene blue; mix well and examine against the light; a mint or emerald-green coloration is positive, whereas any bluish tinge renders the test *negative*. Russo reported the reaction as being unaffected by boiling or by the ingestion of such drugs as calomel, quinin, salol or caffein, and also pointed out that the gradual resumption of the bluish tinge, as the patient advanced in the disease, was a valuable and favorable prognostic sign. During the past year Rolph and Nelson have been employing this test, as a routine proceeding, on most of the cases entering the Toronto General Hospital, and vouch as to its efficacy as a diagnostic aid in typhoid if applied early enough in the disease. Of fifteen patients examined, thirteen gave a positive Russo, eight of these gave a negative Diazo and seven a negative Widal. Two reacted negatively to all three tests. One of these patients furnished a positive blood-culture and had typical symptoms. The other was an unusual case.

There is one important fallibility of the reaction, which at first bothered the authors a great deal, until one of them discovered the cause, viz., that urines containing bilirubin will give a reaction which differs so slightly from the typical green, that they cannot be used in employing the test. Bile should be tested for, and in the event of its presence, the urine should be discarded. The earlier in the disease the more likely and the more typical the reaction. This is very important, as it differs, in this respect, from other laboratory tests, except blood-culture. The slightest tinge of blue must call for a negative interpretation, though experience will often enable one to distinguish the returning blue tint of a convalescent typhoid patient, from that of a normal or nontyphoid urine. The reason of the mint or emerald-green color is doubtful, but it is probably a reduction test, depending on the presence of unknown bodies in the urine. The authors did not find the gradually returning bluish tinge of much assistance in prognosis, as so many of the dangers of typhoid, are, as it were, accidental, and not directly dependent on the severity of the infection.

75. Treatment of Hemorrhoids.—After the usual preparation, Else seizes the center of the posterior quadrant at its apex with forceps and makes an incision from ½ inch above its base to the mucocutaneous line. This incision is made eliptical at the summit of the hemorrhoid, in order that the edges of the mucous membrane may fall together after the dissection. The mucous membrane on one side is now seized with an artery forceps at about the center of the incision and, by producing slight traction on the forceps, with the handle of the scalpel the mucous membrane is freed from the hemorrhoidal mass for about one-eighth of the circumference of the rectum. The same is now done on the opposite side, after which the hemorrhoid-bearing area is dissected from the muscularis, ligated and removed. After all has been removed that can be reached through this incision the mucous membrane is closed with a continuous suture of chromic catgut No. 1, extending into the muscularis, in order to obliterate as much as possible of the space between the two coats. The lateral quadrant having the largest hemorrhoidal mass is now attacked in the same manner, then the opposite side and the anterior quadrant last. Often three longitudinal incisions are found sufficient.

After the operation is completed a simple dressing is placed over the rectum and retained with a T-binder. Else never packs the rectum. On the evening of the second day 2 grains of calomel are given in divided doses and the next morning 1 dram of magnesium sulphate every hour until the bowels move. The movement is preceded with an enema of olive oil. After this a semisolid movement is obtained daily. Else has done this operation several times and has yet to see an imperfect result.

84. Hodgkin's Disease Complicated by Pregnancy.—In December, 1909, the patient, aged 32, v para, began to complain of a burning pain in the right side of the abdomen, which disappeared under treatment for the time being. It returned during the month of February, and continued to the time of admission. This pain was described as dull and aching, extending across the abdomen and into both shoulders, being accompanied at the same time by a feeling of constriction. The pain was always more severe on lying down, so that the patient was compelled to sleep in a Morris chair, which, however, seemed to give relief. About seven weeks before admission to the hospital the patient went to sleep in this chair feeling rather weak but otherwise well and having been able to walk up to this time without any difficulty. On the following morning the patient was unable to get up out of her chair and was never able to walk since that time. At first she could move her thighs and legs but this ability gradually disappeared. The lower extremities were alone affected in this paralysis, the onset of which was unaccompanied by chill, fever or other constitutional disturbance, aside from an indefinite paresthesia. After the patient's admission to the hospital she believed that she was able to feel her feet move and also whenever she "felt life," she said that the legs "were jerked." Involuntary defecation and urination were also present. The paralysis seems to have always been of the flaccid order.

The neck did not show any rigidity, but behind the angle of the jaw and extending beneath the right sterno-mastoid muscle there was a small, soft, lobulated, elastic tumor. This was freely movable and did not seem to be attached to the muscles of the skin. There was no infiltration of the surrounding cellular tissues. Behind the right sterno-mastoid muscle the posterior chain of glands was somewhat enlarged but not tender. The lungs were normal. The heart action was rapid and irregular and the area of cardiac dulness extended from the right border of the sternum to a point about 3½ inches to the left of the midsternal line. There was present a short, faint, systolic murmur, loudest to the left of the sternum in the sixth intercostal space. This was probably hemic in character and otherwise the heart sounds were regular and normal in quality. The abdomen was enlarged by an eight-months' pregnancy with the fetus in R. O. A. position. A diffuse acne was distributed over the back of the thorax and a bed-sore as large as the palm of the hand was present over the sacrum.

The legs were both very edematous, and a flaccid paralysis was present extending from the hips to the feet. There was an absolute anesthesia of the skin of both legs including pressure, heat, cold and pain. This area extended upward over the abdomen to a distinctly marked horizontal line 20 cm. above the symphysis and over the back to about the level of the iliac crests. The rest of the body was normal as regards sensation. The knee-jerks and the knee-clonus were absent. The Babinsky and plantar reflexes were doubtful. Occasionally on pricking the skin of the legs or feet, indefinite muscular twitchings occurred and with each twitch pain in the right side of the abdomen was complained of. May 27, 1910, the patient delivered herself in bed without any previous evidences of oncoming labor. The blood examination showed red cells, 3,880,000; leukocytes, 11,600; hemoglobin, 78 per cent.; neutrophils were increased to 88 per cent., small lymphocytes reduced to 10 per cent.; large lymphocytes to 1.5 per cent.; eosinophils, 0.2 to 1.5 per cent.

The Crile hemolysis test for lymphosarcoma proved negative. Von Pirquet's test was then employed twice and proved negative each time. Examination of the sputum was negative as regards the finding of tubercle bacilli. Finally a Wassermann reaction was done, likewise with negative results. It was then decided to remove a small portion of the enlarged gland under cocain for purposes of diagnosis. Sections of this tissue warranted a diagnosis of Hodgkin's disease. The cause of death was toxemia due to miliary abscesses of the kidney, cystitis and absorption from atrophic ulcers. The abscesses and ulcers were caused by paralysis due to pressure on the spinal cord by a Hodgkin's granuloma affecting the lymph-nodes situated in the posterior part of the dorsal canal. It is generally conceded that Hodgkin's disease is not accompanied by the formation of metastatic deposits in the manner which usually results in the presence of malignant new growths. The enlargements take place only in previously existing lymph-nodes and may occur in any part of the body. The condition noted in this case, in which paraplegia was caused by the involvement of the lymphatic structure in the spinal canal, is very unusual and it seems that only one other case of Hodgkin's disease can be found on record in which this complication took place, that single instance having been reported by Osler.

88. **Puerperal Infection.**—The treatment followed in the New York Lying-In Hospital when the temperature rises after labor is outlined by Harrar. Breast, lung and throat conditions, pyelitis, malaria and typhoid are ruled out. A cathartic is given and attention is paid to emptying the bladder. A full condition of either bladder or rectum interferes with proper contraction and drainage of the uterus. When there has been a recent perineorrhapy the wound is inspected and stitches removed if there is much tenderness or edema. The abdomen is examined, noting height of the fundus, areas of tenderness or resistance and whether there is tympanites or rigidity present. If there is a high rise of the pulse-rate accompanying the temperature, cultures are taken from the cervix and uterus whether the lochia is foul or not. At this procedure inspection can be made of the vagina and cervix, especially noting if the latter is distinctly patulous and gaping. Such a condition of the cervix points to retained portions of membrane or placenta. If the pulse rise is slight in comparison with the temperature rise no vaginal inspection or cultures are made. After this preliminary information has been obtained, the bed is elevated sharply at the head and an ice-bag induces a better tone in the uterus, possibly somewhat inhibits bacterial growth, and certainly gives great relief to the patient if there is any pain. If the temperature remains high or recurs, and the gonococcus or the streptococcus be reported, the former treatment is simply continued. If the colon bacillus is found or "no growth" reported and the lochia is foul, give a gentle intrauterine douche. At this time with the continuance of temperature and in the absence of the gonococcus or streptococcus it is permissible to make a gentle digital exploration of the interior of the uterus and remove any fragments of secundines that are present or release possibly retained lochia. This is in no sense of the word a curettage. Harrar says: Never curet, except in incomplete abortions at or before the third month. The further course of the treatment depends on the development of the case and already has been suggested in the description of the various conditions that may arise in bacterial infection of puerperal women.

89. **Multiple Cesarean Section.**—Thirty cases were done for the second time, seven for the third time, and one each for the fourth and fifth times. In eighteen cases there were no adhesions present at all, in eleven very few, in several there were many, in one the uterus was adherent to the abdominal wall and in two cases no note was made. The uterine scar of former operations was not seen in nine cases, was normal (not thinner than the rest of the uterus), in twenty-five cases, was very thin in four cases, and was ruptured in one case, the latter being one in which many adhesions were noted. In the series there were three deaths of mothers; one from anesthesia, occurring on the table before the uterus was opened, the second from sepsis on the third day and the third from pneumonia on the fifth day. One child died of hemophilia on the sixth day. Thus it is observed that the repeated operation offers very little danger over the primary and that in cases in which some obstruction to labor exists, such, for example, as contracted pelves, there is no logical reason why the patient should not become the mother of a normal family with periods of quiescence and comfort between pregnancies, making the operation of sterilization unnecessary and, in McPherson's opinion, as a routine measure distinctly unjustifiable.

7 *New Form of Trochiscus Sir J. Sawyer.

4. **Complete Gastrectomy.**—In December, 1907, Moynihan recorded a case of complete gastrectomy. The patient was a man, aged 43, who had suffered for two years from gradually increasing distress after food. At the operation a small, greatly thickened stomach was found, and as no healthy part of its wall could be discerned the whole organ was removed. The cut end of the esophagus was stitched to the side of a loop of jejunum, brought upwards through an opening in the transverse mesocolon. The pathologic report stated that the stomach was involved in a neoplastic change of a particular type which has its analogue in the so-called atrophic scirrhus met with in the mammary gland. The patient made a good recovery from the operation.

During the three years and eight months that he lived after the operation he was under constant observation. He was perfectly well up to the early part of the year 1910, when he began to show the evidences of a profound anemia. He was strikingly pale and breathless, and he lost weight. Under treatment, however, he improved, and in May, 1910, his color had returned and he was able to ride and drive and attend to matters on the farm. In August, 1910, he began to fail again; he became easily tired, though he still tried to carry out the greater part of his work. His appetite remained good and he had no indigestion. In October, the signs of anemia reappeared, he grew much weaker, and had to cease work. He began again to lose weight, his appetite vanished, and he vomited occasionally. There were no abnormal signs of any kind in the chest or abdomen throughout the illness. Soon after Christmas, 1910, he had to take to his bed, and he died on the last day of January, 1911. He had gained 38 pounds after the operation and he held the gain for nearly three years. His appetite was good, he experienced the sensation of hunger, and he was able to eat the ordinary foods; but he had to take a rather longer time over a meal than in the days preceding his original illness. The chief points of interest in the case are: (1) Complete absence of any recurrence or dissemination; (2) the very profound anemia; and (3) absence of any striking jejunal dilatation at or near the site of anastomosis.

7. **New Form of Trochiscus.**—Sawyer suggests the assimilation into medical practice of the excellent pharmacologic basis afforded us by the popular modern sweetmeat known as the "chocolate cream." The following prescription illustrates its use:

℞	Gm. or c.c.		
Mentholis	006		gr.1/10
Olei eucalypti	003	or	♏ 1/5
Pastæ lactis			
Pastæ nuclei cacao, āā q. s.			

Fiat trochiscus, sec. artem.

Or the pasta lactis in each trochiscus may be medicated by the addition of 1 or 2 grains of borax, or ½ grain of sulphate of zinc, or 1 minim of oil of turpentine, or of oil of cajuput, or ½ minim of oil of anise. Sawyer suggests that the trochisci might be called cremules and, Latinized, cremulæ. When quickness of preparation is to be wished for, unmedicated ones can be medicated readily by remedies which are liquid in their form, by injecting a minim or so of the medicament into the center of a "simple" cremule, by the aid of a hypodermic syringe.

12 *Mode of Transmission of Leprosy. T. L. Sandes.
13 Infant Feeding in the Tropics. W. E. Deeks.

12. **Transmission of Leprosy.**—Considering the enormous numbers of lepra bacilli in the infiltrated or ulcerated skin and nasal mucosa of an active "tubercular" leper and the ingestion of bacilli by certain insects, Sandes suggests that direct contact and transmission by flies, fleas, mosquitoes or other insects are possible modes of spread of the disease; but such infection, if it ever does take place, is accidental and exceptional. Having found acid-fast bacilli answering, as far as our imperfect tests permit, to the characteristics of lepra bacilli in a considerable proportion (about 30 per cent. of specimens of *Acanthia lectularia* up to sixteen days after feeding on lepers) there is reason to believe that this species of insect constitutes a very important agent in the spreading of leprosy.

H. M., aged at the time, 11 years (whose father had been removed as a leper to the asylum some time previously and whom the son used frequently to visit), observed for the first time in the year 1901 a small, red papule under his chin. It enlarged slowly, becoming in area, to use his own simile, about the size of a 6-penny piece. It was indurated and resistant to treatment. It remained thus, slightly raised, hard, and of a reddish hue, for two complete years before any further symptoms appeared. In 1903, he noticed for the first time a bluish puffiness of his cheeks, later slight thickening of his eyebrows, and a diffuse but moderate swelling of the entire countenance. Toward the end of the year tubercles began to appear on his face. Thereafter tubercles continued to appear at irregular intervals on his face. The glands of his neck became involved. From this time onward the tubercles and other typical signs were of universal distribution and showed a diffuse systematic infection. Sandes believes that the initial pimple, and later tubercle, on the chin would appear to have been the primary lesion, probably caused by the bite of a leprosy-infected bug.

14 Pelvic Cysts Due to Spinal Meningocele. J. S. Fairbairn.
15 *Retraction Ring as Cause of Obstruction in Labor. R. Jardine.
16 Dysmenorrhea; Hematometra of One Horn of Uterus Bicornis. E. Maclean.
17 Secondary Abdominal Pregnancy—Fourth Month. G. Fitz-Gibbon.

15. **Retraction Ring Cause of Obstruction in Labor.**—In an obstructed labor, when the retraction ring can be palpated through the abdominal wall, Jardine regards this as a danger signal which must not be disregarded. Prompt and proper treatment must be adopted, or rupture of the uterus will soon occur. If improper treatment is adopted, the rupture may be caused by it. In ordinary cases of obstructed labor the ring is not the primary cause of the obstrucction, but rather the result. Occasionally, however, cases occur in which the ring is the cause of obstruction. In some of these cases the ring actually forms in front of the presenting part, while in others, it is behind the presenting part, which may be either the head or the breech. In obstructed labors the ring is due to excessive retraction of the main body of the uterus and thinning out of the lower uterine segment. In such cases it naturally follows that there must be a very palpable ledge where the thinned out lower uterine segment becomes continuous with the retracted and thickened main portion of the uterus. By an internal examination, the ring can be recognized before it can be palpated through the abdomen. There is no apparent obstruction from a contracted pelvis, tumor or an abnormal presentation, and yet the labor is delayed, although the uterine contractions are strong and frequent. The uterus may be in a tetanic condition without any relaxation between the pains. On palpating the abdomen, one finds that the presenting part is above the brim of the pelvis, but may not be able to feel the retraction ring. On making a vaginal examination the os is dilated, and the lower uterine segment opened up, but some 3 inches or so above the os, there will be a distinct ledge running round a portion of the whole of the uterine cavity in front of the presenting part. During a pain, this ledge will not relax, but it will contract, and prevent any advance of the presenting part. The membranes may or may not be ruptured. If they are intact, they will protrude into the vagina, and they may even be seen at the vulva. The condition is an exceedingly dangerous one for both mother and child. If it is recognized in time, both may be saved, but in most of the recorded cases, a definite diagnosis was only made when exhaustion had set in, and there was little chance of saving either mother or child. If the condition is recognized in time, and proper treatment is adopted, both mother and child should be saved, in the great majority of the cases.

As for treatment, give the patient a full dose of morphin, and when she is fully under the influence of the opiate, if the ring has not relaxed, anesthetize her deeply, dilate the ring manually and deliver with forceps. If one cannot dilate the ring manually, perform Cesarean section, if the child is still alive. Incision of the ring has been advised, but it will almost inevitably end in rupture of the uterus. If the child is dead, a craniotomy should be done, and delivery by means of an instrument which will thoroughly crush the head. If the shoulders obstruct, cut the clavicles, to allow the shoulder girdle to collapse. Hydrostatic bags have been advised to dilate the ring, but they are useless, as one cannot introduce them high enough to bear on the ring. When the ring is above the presenting part, in the majority of cases, there will be another obstruction, such as a contracted pelvis, a tumor, or a transverse presentation. These cases should be dealt with according to the rules laid down for the treatment of such obstructions.

25 Averages of Weight and Chest Measurements of 705 Madras Coolies. B. Nicol.
26 Hydrocele. T. H. Foulkes.
27 An Anopheline Allied to Myzomyia Listoni. U. N. Brahmachari.

21. **Vaccine Treatment of Leprosy.**—Five of the twelve patients treated by Rost with this vaccine are now practically cured as far as clinical observation goes, while the remaining seven are all remarkably improved. The vaccine was injected weekly, and temperature records taken almost always showed a rise of temperature varying from 100 to 105 F. Rost has been using all along 1 c.c. of a 1 in 400 dilution of dried culture or the equivalent thereof, and 1 c.c. of a sterilized six-weeks' broth culture. He has found it to be advisable to obtain only slight reactions in nodular cases, whereas in anesthetic cases the higher the reaction, the better the result. The reason for this probably lies in the fact that in the anesthetic cases the bacilli being situated in the nerves, there is not the danger of metastasis that there is in the large masses of the nodular variety. The improvement after vaccine injection may come on gradually some months after injection. With the idea of trying to ascertain the interval at which injections should be given, opsonic indices were taken of treated cases, but the time at his disposal in this laborious research precluded the possibility of arriving at any result which one might rely on, and he had to judge the period from clinical observation of the treated patients. It is also probable that the time at which the vaccine should be repeated varies according to the case.

22. **Endemic Goiter.**—McCarrison has been employing vaccines in the treatment of goiter with good results. A coliform organism grown from the feces of sufferers from the disease has usually been employed for the manufacture of the vaccine. He gives this vaccine in doses of from 150,000,000 to 300,000,000 at intervals of from seven to ten days, and has found that five or six inoculations is all that is required to cause a complete disappearance of the swelling. In some recent cases as few as two inoculations were sufficient. This treatment is popular with the people as it does not involve the taking of medicines two or three times a day, and apart from the slight discomfort at the site of inoculation for twelve hours or so, the patient is free to follow his usual avocations. A portion of the skin of the upper arm is painted with iodin tincture and the inoculation made without any further preliminary sterilization of the skin. An autogenous vaccine is on the whole more useful that a stock vaccine, but McGarrison found the latter to act admirably. He says he cannot as yet attribute any specific action to the organism from which the vaccine is prepared. But so far at least as goiter is concerned, the efficacy of a vaccine does not depend on the specific nature of the organism from which it is prepared. He has employed other vaccines and in some cases with surprising results. One patient was successfully treated with a staphylococcus vaccine. The result could hardly be better. The staphylococcus was taken from a diseased femur in a *non-goitrous* individual. Three inoculations of 250,000,000 caused the bone to heal and the discharging sinuses to close up, while it took five doses to bring about the change in the goitrous individual shown in the figures. *Staphylococcus albus* is certainly not the cause of goiter, yet a vaccine prepared from it can cure the disease.

30 *Clinical Reports of the Rotunda Lying-In Hospital, Dublin, 1909-1910. E. H. Tweedy and R. J. Rowlette.

30. Clinical Reports of the Rotunda Lying-In Hospital.—One hundred and sixty-one abdominal sections were performed in the Rotunda Hospital and in twenty cases the abdomen was opened through the vagina. Sixteen of these were vaginal fixations. Fourteen abdominal myomectomies were performed. Several of these necessitated the almost complete division of the uterus, and the recovery in all cases was uneventful. Two of these patients, who had come to the hospital because of sterility, have since been successfully delivered. There were ten Wertheim operations with one death. Tweedy thinks this operation should be performed when practicable in all cases of uterine cancer, whether of the body or cervix. He operated for the cure of complete tears fourteen times, with uniform success after the first operation. There were also performed eighty-five trachelorrhaphies and amputations; fifty-six ventral and sixteen vaginal suspensions; thirty-five hysterectomies; forty-seven vaginal operations; seventy-two operations on the ovaries and tubes. Eleven hysterectomies were done for malignant disease—seven cases of epithelioma of cervix, two of adenocarcinoma of the body and one sarcoma of the body. Only one of these patients, aged 60, died—a case of epithelioma of the cervix in which a Wertheim operation was done. The cause of death was congestion of the lungs. The ages of the others ranged from 35 to 61. Only five of the 504 patients operated on died. The causes of death were sloughing of spleen after subphrenic abscess, abdominal cancer, general peritonitis, congestion of lungs and septicemia. One of the cases of adenocarcinoma of the uterus was of interest in that two ovarian cysts were present, in one of which were masses of the same nature as the tissue in the uterus. Sarcoma of the uterus is a comparatively rare condition. This is only the third specimen met in six years' practice at the Rotunda. The tumor was a large, soft, homogeneous mass, situated, as nearly all these tumors are, in the endometrium of the fundus. It had infiltrated the wall of the uterus, so that it was invading the peritoneum and forming adhesions with neighboring viscera. Microscopically, it consisted of irregular, large, round cells. One of the cases of ectopic pregnancy was of special interest in that it is the first recorded case in Ireland of true primary ovarian pregnancy. Of twenty-one cases of inflammation of the tubes examined, six were tuberculous. The proportion in six years has been fifty-three and nineteen. A point of some interest is the frequency with which cysts of the ovary are related to chronic salpingitis. In four of the cases this year small cysts of the ovary occurred, i. e., in about 33 per cent. of the cases of chronic salpingitis, non-tuberculous in origin. Twenty-five cystic conditions of the ovary were examined; fifteen of these specimens were ordinary multilocular, smooth-walled cysts, one was a simple papillary cyst, and three were malignant papillary cysts; three lutein cysts are in the number, and three dermoids. Two dermoids occurred in one patient. Another dermoid examined was in part malignant. In addition to the three cases of malignant papilloma and this case of malignant dermoid, two other cases of malignant disease of the ovary were encountered. As usual in primary cancer of the ovary, the disease was bilateral. No primary focus of disease elsewhere in the body could be discovered.

31 Tracheobronchial Glandular Disease. (Adénopathie trachéo-bronchique.) H. Barbier.
32 *Diet for Dyspeptic Children. (Régime des grands enfants dyspeptiques.) H. Legrand.

32. Diet for Children Inclined to Dyspepsia.—Legrand's article is a detailed review of food adapted for school children of all ages with recipes for numerous dainty French dishes. He lays great stress on passing certain dishes through a very fine "silk" sieve, especially beans, peas and green vegetables to form a digestible purée. The butter or cream should not be added, he says, until just as the dish is served. Potato should never be allowed a dyspeptic except mashed or in a soufflé. Bread should be allowed only in small quantities to dyspeptic children, and only very well cooked or toasted. Not much raw fruit should be allowed; the preference should be given to stewed fruits or jellies not very much sweetened. The dyspeptic should never drink at the commencement of a meal and very little through the meal, but between meals skimmed milk and kefir may be allowed. A rest after eating, immaculate condition of the teeth and slow chewing are indispensable for dyspeptic children. He adds the yolks of eggs and butter to certain soft mashed vegetables just as they are served, thus increasing the palatability and nourishing value. He commends in particular frogs' legs and poached yolks alone as particularly digestible. Very little soup should be taken as it has small nutritive value while it dilates the stomach. He expatiates further on the importance of actually fresh eggs for dyspeptics; the more recently laid the more easily digested and the less likely to induce putrefaction in the intestines.

Journal de Chirurgie, Paris

33 *Primary Sarcomas of the Muscles—Myomectomy. (La myectomie large dans certains sarcomes primitifs musculaires.) P. Lecène and L. Mondor.

33. Primary Sarcoma of the Muscles.—Lecène and Mondor report a case each of sarcoma of the muscle of the thigh or leg, both patients apparently cured by extensive resection of the muscles into absolutely sound tissue regardless of possible functional trouble afterward. Twelve similar operations are on record. Only five of the total fourteen patients were women; one was a girl of 17, two about 22 and the others 40 and 58 years old. There has been no recurrence in any case during the three to eight years since the operation, but one patient has died of intercurrent heart disease. As is shown in an illustration, sarcomas in muscle tissue have something like a capsule around them, but it would be a grave mistake to restrict the operation to this; the muscle should be resected far beyond on all sides. The functional disturbances from the mutilation always proved surprisingly slight.

37 *Ultimate Results of Operative Treatment of Exophthalmic Goiter. (Les résultats éloignés des interventions thyroidiennes dans la maladie de Basedow.) H. Alamartine and E Perrin.

34. Inflammatory Tumor of the Stomach.—Mouisset and Delore report a case of duodenal ulcer in which gastro-enterostomy was followed by development of a large tumor in the epigastrium, hard and irregular, accompanied by anemia. Under medical measures the tumefaction subsided and the patient, a man of 39, has been in fairly good health during the year to date, although the primary trouble was suspicious of cancer and the primary deep tumor in the duodenum is still palpable.

37. Ultimate Results of Operative Treatment of Exophthalmic Goiter.—Alamartine and Perrin summarize 120 cases of exophthalmic goiter in which an operation was done over three years ago as reported by seven different surgeons. In eighty-five cases the cure was complete, that is, in 70.8 per cent., while there was marked improvement in twenty-seven other cases, that is, 22 per cent., and only 6.6 per cent. of the patients were not benefited. Even when the goiter persisted yet the conditions in regard to the circulation were so modified that the special symptoms subsided permanently.

46 Action of Calcium Chlorid as a Diuretic in Nephritis. G. Vitry.
47 Technic of Blood Transfusion. S. Voronoff.

39. **Action of Salvarsan on the Acoustic Nerve.**—David reports one case in which a defect of hearing appeared after the administration of salvarsan for a secondary syphilis. The injection was subcutaneous, a dose of 0.45 gm. (7 grains) being given. The ear symptoms appeared seven weeks later. The author has been able to collect twenty-eight other cases in which the acoustic nerve has been attacked after the administration of salvarsan. The reaction of Herxheimer which has been invoked does not afford a satisfactory explanation, neither is there evidence of a syphilitic relapse in these cases. In David's case both the blood and cerebrospinal fluid were negative to the Wassermann reaction. David suggests that salvarsan has special affinity for the nervous system, due to some product of decomposition and that in cases in which the ear affection comes on late, a storage of arsenic has occurred, probably in the liver. The ear trouble is likely to occur after all methods of injection. Another case has been reported by Beck in which hearing was partially recovered by the use of pilocarpin.

41. **Epidemic Relations of Pneumonic and Bubonic Plague.**—Broca brings forward evidence to show that epidemics of pneumonic plague occur in winter and those of bubonic form are found in summer. Epidemic pneumonic plague does not appear to be known in warm climates. The explanation of these facts appears to lie in the fact that the bacilli of pneumonic plague are highly virulent and are spread by means of human contagion without the intervention of the rat, while in the summer time when the insect carriers of the disease are able to infect the rat population, inoculation on the skin producing buboes is the most likely mode of infection and the epidemics of summer and of warm countries exhibit the bubonic type. Consequently during the summer and in hot climates the prophylactic measure chiefly to be employed is the destruction of rats and their infesting parasites, human contagion playing an insignificant rôle, while in winter quarantine and isolation must receive greater attention.

42. **Cysts of the Cerebellum.**—Chauvet and Velter discuss the symptomatology of cysts of the cerebellum and note that at times such a cyst runs its course without characteristic symptoms, the only complaints being such as are common to brain tumors in general. They report such a case, with necropsy. The cyst had developed in a glioma. Histologic researches on the rest of the cerebellum are promised. The authors suggest that in this way the absence of focal symptoms may be explained.

44. **Rôle of the Interosseous Membrane in Overriding of Fragments in Fracture of the Bones of the Leg.**—Saissi recalls the well-known difficulty of reducing fractures of the bones of the leg in which the fragments override, a difficulty which has usually been attributed to the contraction of the muscles. He has shown by experiment on the cadaver that it is the tension of the interosseous membrane which causes the difficulty. He sawed the bones in two, separating the tibia below and the fibula above in one case, and both bones at a low point in the other. In the first case he found a shortening and deviation of the lower fragment slightly outward so that the upper part of the interosseous membrane was put on the stretch. This was so pronounced that attempts to reduce the displacement by traction in a vertical direction caused the membrane to tear in almost its entire length. In the second case, it was practically impossible to effect the reduction by traction downward. He concludes that the membrane alone is sufficient to hinder the reduction of the overriding fragments in this fracture. With the view of obviating this difficulty, he devised the following maneuver which he has carried out experimentally, but so far has had no opportunity to put into practice. Taking the lower fragment of the tibia as an axis, he makes strong external rotation with the view of relaxing the interosseous membrane, then makes traction downward to draw down the displaced fragment, after which an internal rotation brings the two parts of the tibia into apposition.

Progres Médical

August 5, No. 31

48 *Panoptosis. E. Ledoux and Tisserand.

48. **Panoptosis.**—Ledoux and Tisserand discuss the nature of the syndrome represented by a general ptosis of the abdominal organs, a condition of atony and relaxation of the tissues in general, and nervous reactions, both local and general, a form of neurasthenia. While the theoretic explanations of this condition are generally unsatisfactory, the authors believe they have established in the majority of their patients an insufficiency of the thyroid, and from further observations, they conclude that the essential metabolic change is a demineralization and chiefly, a decalcification of the tissues. Acting on this supposition they have administered lime salts with apparently marked success. They are so convinced of the value of this treatment that they attribute to it a therapeutic diagnostic importance. Every patient suspected of belonging to this class they claim will show distinct, rapid and considerable improvement under recalcification, if the diagnosis is correct.

60. **Rhizotomy.**—Guleke has performed this operation five times in the last year for gastric crises and the immediate

benefit was amazing, he declares. There were no further pains or vomiting and the patients were soon weaned from their morphin. But this gratifying phase did not last more than a month or so before symptoms developed indicating intestinal crises. In one patient they were so severe that Guleke resected further the tenth and eleventh roots. In the others the intestinal crises were minimal or bearable in comparison to the former condition of the patient. The outcome of the rhizotomy is thus liable to be somewhat disappointing, but this possibly may be due to the preexisting chronic morphin poisoning; if the operation could be done before the drug addiction the results might prove incomparably better. The main point now in differentiation is to learn to distinguish between vagus and sympathetic gastric crises, as only the latter are amenable to rhizotomy.

61. **Atrophy of the Prostate.**—Barth has operated in two cases of senile atrophy of the prostate causing severe symptoms, incontinence alternating with retention, the urine infected and catheterization often necessary. Both patients were restored to normal conditions in respect to their urinary apparatus after prostatectomy. The prostate was found shriveled to two small bunches scarcely as large as a bean, with numerous adhesions to the surrounding tissue. The excellent outcome, he remarks, shows that we no longer need feel so helpless in the presence of senile atrophy of the prostate; prostatectomy promises as good results here as with an enlarged prostate. The vesical sphincter is probably suffering from the same atrophy as the prostate, but all trouble from this source is obviated when the fibrous ring at the neck of the bladder is removed. It is possible that a Bottini operation on this fibrous ring might answer the purpose without further intervention. Fuller has reported three cases which seem to sustain this assumption. His patients were between the ages of 37 and 45 and all were cured by merely slitting, through a perineal incision, the hard ring at the neck of the bladder. There was a history of gonorrhea in two of these cases, as also in one of Barth's.

63. **Ligation of Branches of Pulmonary Artery to Act on Lung.**—Schumacher declares that the results of three years of experimental research on cats, dogs, goats and sheep and two clinical experiences have all demonstrated that by shutting off part of the lung from the circulation by ligating its arteries, intense proliferation of connective tissue follows and the part of the lung involved becomes a hard, tough mass. He shows in ten illustrations the best technic for the ligation, and discusses the outlook in its application in treatment of lesions of the lung. There is already, he insists, no doubt of the advantages it offers as a preliminary to resection of a tumor in the lung or a plastic operation on the thorax.

65. **Atony of the Cecum.**—Klemm refers to the cases generally classed as chronic appendicitis but in which the disturbances persist after appendectomy. He ascribes the trouble to some obstruction to the outflow of the secretion in the appenaix. The result is a slight inflammation, too mild to induce symptoms but serious enough to injure in turn the serosa of the cecum and impair the elasticity of the bowel wall, which stretches and atony follows as the feces stagnate here. The cecum may not be abnormally movable but its stretched walls sag; the best remedy is to take up a fold in the wall.

67. **Movable Cecum.**—Wilms ascribes the syndrome generally called chronic appendicitis to various anomalies affecting the cecum, abnormal length, size, adhesions, kinking, etc., most of which can be remedied by suturing the cecum in its proper place. In fifty-two cases in which he did this between 1907 and 1909, 75 per cent. of the patients were freed from all their disturbances, including their tendency to constipation. In six more recent cases the cecum was so abnormally large that he concluded to exclude it altogether, and the patients since have been free from all disturbances.

68. **Treatment of Cancer.**—Werner states that at the Heidelberg Cancer Institute the experiences with 2,000 cases of cancer have led to the adoption of the following outline of treatment. A radical operation is the rule whenever possible except for certain forms of sarcomas and epitheliomas which yield to radiotherapy or arsenic. The radical operation is not done with the knife but with the electric needle (de Forest's), especially when conditions interfere with excision far into sound tissue. Equally important is it to keep the wound open so that the Roentgen rays can be effectually applied. Fully 60 or 70 per cent. of all recurrences of cancer occur in the field of operation, and here is where improvement in technic is needed. Active immunization with the patient's own tumor material seems to offer encouraging prospects for warding off metastasis, but further experience is necessary to determine its harmlessness before it can be generally recommended. If a radical operation is not practicable at once, the cancer should be eventrated or exposed in some other way, so that it can be submitted to roentgenotherapy.

70. **Experimental Research on Exophthalmic Goiter.**—Klose injected dogs with the juice squeezed from goiter taken from patients with the exophthalmic form. The animals developed constantly a transient syndrome with the blood-findings of exophthalmic goiter, and exophthalmos in some instances. Comparison of the facts observed in the experiments and in the clinic seems to demonstrate that exophthalmic goiter is not due to excessive but to perverted thyroid functioning. The thyroid seems to be unable to collect and store the iodin in its normal form of iodothyrin but only in the form which might be called the Basedow form. In this form it exerts the same action as inorganic iodin injected into a vein. The theory thus elaborated harmonizes with and explains empirical observations and data.

74. **Experiences with "Slip Hernia."**—Sprengel defines the *hernie par glissement* as one in which a segment of the colon with no mesocolon or a very short one, is drawn into or slips into a hernial sac by the inclusion in the sac of the parietal peritoneum to which it is attached. He describes the mechanism involved and states that three of his thirteen patients in this category died soon after the operation, from peritonitis.

77. **Etiology of Splenic Cysts.**—In a case of splenic cyst cited by Küstner, a woman, aged 39, had noticed a tumor the size of a head in the left hypochondriac region which had caused her considerable pain. This condition had existed for two years when the author decided to extirpate what he considered to be a cyst of the spleen. The result was an entirely successful one. The patient was discharged on the sixteenth day after the operation with a blood count of 23,000 leukocytes, 6,000,000 erythrocytes and 72 per cent. of hemoglobin. Three and a fourth years after the operation the patient is entirely well and is able to carry on her work. There have never been any nutritional disturbances or gland swellings. Four-fifths of the spleen in this case was occupied by the cyst which contained a sulphur-yellow fluid. Echinococcus cyst was ruled out. It is evident then that in this case splenic function had ceased long before the splenectomy was done so that the patient's economy had easily come to do without the spleen, to which fact the author ascribes the good results after the operation. As a cause of the condition in this case it is suggested that a twisted pedicle which was found at the operation was responsible.

78. **Iodin in Gonorrheal Arthritis.**—Hildebrand reports very favorable results from the injection of tincture of iodin into a joint that is the seat of a gonorrheal arthritis. For several

days after the injection the swelling increases notably and then disappears very rapidly. The pain subsides quickly, no new fluid is formed and motion is restored. He has used this method for nine months and thinks well of it. He cautions against using too much iodin. He injects a 5 per cent. solution.

81. **Vegetable Albumin in Diabetes.**—Experimental research and clinical observation have convinced Blum that vegetable albumin is a far more useful component of a diabetic diet than meat albumin. He suggests that the former be substituted for the latter more often than has been done heretofore.

88. **Anemia in Nephritis.**—Pribram is of the opinion that in nephritis the retention of poisonous products serves to stimulate the function of the adrenals, thus leading to the production in excess of adrenal secretion. The retention in turn of this secretion leads to anemia. The author offers this as a solution for the occurrence of anemia in nephritis.

91. **Tolerance of Infants for Morphin.**—Wichura reports the case of a three months' old child whose father gave to it, by mistake about 2 centigrams of morphin. The child went to sleep at once. An hour after the mother became alarmed at the appearance and condition of the child and sought the aid of the author. The stomach was washed out at once and other measures of resuscitation were employed. Sixteen hours after the ingestion of the morphin the child was in a fairly good condition and on the following day had recovered entirely. The author points out that this case illustrates the fact that the usually assumed intolerance in infants for morphin is not always correct. This child was given more than twenty times the dose for an infant of its age and one hour elapsed before any measures to resuscitate were resorted to so that the initial gastric lavage would not contribute in large measure to the recovery of the child. Wichuria therefore believes that he is justified in assuming that this was a case of extreme tolerance for morphin.

101. **Theory of Menstruation.**—Görl reaches the conclusion that the internal secretion of the ovary first appears at puberty and that it leads to the development of the secondary sexual characteristics. At the time of the maturation of an ovum this secretion is changed in slight degree so that it cannot enter into combination with antagonistic substances and then menstruation occurs. A change in the chemical composition of the secretion or disturbances caused by irregular maturation of the ova will produce menstrual disturbances, and even lead to the formation of uterine myomas and cardiac disturbances. In other words, the condition produced may simulate shock. The internal secretion of the ovary is held to be a most important one and is believed to be related to disturbances both general and local.

106. **Salvarsan Accident.**—Three days after the intravenous injection of salvarsan the patient, whose history is given by Mann, became unconscious, with complete loss of all reflexes and sensibilities. This condition lasted for three days when it subsided gradually.

107. **Displacement of Larynx.**—In a case of pulmonary tuberculosis involving the right apex, extensive contraction of lung tissue displaced the larynx, pulling it over as far as the sternocleidomastoid muscle. There was no anatomic change in the larynx or thyroid. The median line of the larynx was directed toward the right, and the left cornu of the hyoid bone was very prominent. The extreme weakness of the patient made an extensive and thorough examination impossible.

117 Simplified and Improved Technic for Extraperitoneal Cesarean Section. H. Sellheim.
118 Serotherapy of Puerperal Sepsis. G. Bohnstedt.

114. **Urogenital Tuberculosis.**—Krönig comments on the wide divergence of views expressed at the recent Gynäkologen-Kongress on this subject, which was the main topic appointed for discussion. It was stated there that over 60 per cent. of the women with urogenital tuberculosis are under 30 and the primary operative mortality ranges from 10 to 13 per cent., while many clinicians have not observed that the general health seems to suffer very much from the urogenital tuberculosis. The point now is to compare the ultimate outcome in the operative cases with that under expectant treatment. This will decide the question. To date only one thing seems established beyond question, namely, that removal of the one kidney affected with tuberculosis gives brilliant results if done in the earliest stages.

115. **Diagnosis of Retroversion of the Gravid Uterus.**—Graefe states that sixty-one of his 200 patients in this class had no disturbances from their retroversion. The anomaly corrects itself in a large proportion of cases, but as it is impossible to foresee whether this will occur, he advises a pessary, especially if there is a history of preceding abortions. Spreading the fingers in the vagina, in front of the pessary, sometimes corrects the retroversion as also the ventral decubitus or knee-chest position. In seven cases the uterus was held down by adhesions, which he was generally able to correct by manipulations from without but a laparotomy was required in one case.

122 Double Pelvis in Right Kidney. (Doppeltes Nierenbecken, das eine infiziert, das andere gesund.) W. Stark.

119. **Chronic Proliferating Urethritis.**—Lohnstein announced a while ago that the reason why gonorrheal urethritis in certain cases proves so rebellious to treatment is because the mucosa has thrown up ridges behind which infection still lurks or actual polyps or papillomas have developed. These proliferations cause no subjective disturbances, but treatment is ineffectual until they are removed or the parts are other-

wise sterilized. He has devised several instruments for visual inspection and cauterization or curetting, and he relates a number of cases showing their advantages and the cures he has realized with them in cases which would previously have been deemed incurable. In one case severe chronic prostatitis with diffuse proliferating inflammation of the posterior urethra simulated chronic retention from enlargement of the prostate. An incision with his incisor-urethroscope in the middle and right lobes put an end to all the symptoms. His treatment failed in four cases, owing to constant recurrence of papillomas without continuous medical supervision.

120. Chromocystoscopy.—Roth reports some experiences which show that the indigo-carmin method of testing the functioning of the kidney is less reliable than the old methods of cryoscopy and phloridizin glycosuria. Cryoscopy fails in all cases in which there is no functional disturbance. For these, catheterization of the uterus is the only means of obtaining information. The indigo-carmin method is instructive only in the cases of advanced disease while changes in the freezing-point and the phloridizin method show pathologic conditions in their incipiency in most cases. There is one exception to this, however, he adds; with calculi in the kidney the indigo-carmin method may give valuable information beyond that attainable with any other technic. With enlargement of the prostate and with retention of urine the indigo-carmin method is liable to do good service as a preliminary to operative treatment, but it is seldom necessary as the urine can be drawn with a catheter from the bladder without the need for the test.

123 *Foot Sign of Meningitis. (Il tono del piede.) L. Minervini.

123. Ankle Sign of Meningitis.—Minervini has found it possible to elicit a sign of meningitis with the foot which seems to be the equivalent for the Kernig sign and to be the opposite of the ankle clonus. It is much easier to apply the test to the foot than the Kernig technic to the leg, and the interpretation of both seems to be the same. He found the foot tonus, as he calls it, pronounced in a typical case of tuberculous meningitis in a young man, reported in detail, confirmed by necropsy, and in a case of hysteric astasia-abasia, but it was absent in a case of infantile spinal paralysis, its absence here confirming its significance in the other cases. The ankle is grasped with one hand and the toes with the other, and the foot is bent up toward the knee with a forcible push. When the phenomenon does not exist the foot drops back again as soon as it is released, but in case of the pathognomonic reflex contraction, the flexion persists. This ankle tonus is frequently found in inverse proportion to the knee-jerk. It seems to be merely an exaggeration of the normal muscular tonicity, and thus he has encountered it in meningitis, sciatica, spastic tabes and hysteria.

THE RELATION OF THE MEDICAL PRACTITIONER TO HEALTH DEPARTMENTS *

W. A. EVANS, M.S., M.D., LL.D., D.P.H.
CHICAGO

CHAIRMAN'S ADDRESS

As a general proposition we are willing to earn a thing but once. When a man has served years in an association, he sometimes comes to think he has earned its rewards. If, then, an office is bestowed on him he is likely to accept it as his just due and to give the duties of his position none of his brains or energy.

I have not done enough work in this Section to have earned reward at your hands, therefore, I have felt it incumbent on me to earn the honor which you have given me, by work as chairman.

Dr. Jones and I have worked out a somewhat novel plan for your meeting. This plan was submitted to the Executive Committee of this Section, Drs. Hurty, White and Gorgas, and then it had the approval of the general officers of the Association.

We submit it to you with this understanding: The responsibility for its success or failure rests on you who are in attendance on this meeting, and is shared by those who are to attend subsequent meetings.

The plan for this meeting has three parts. The first part is that in place of papers there will be committee reports on health methods. The Section will carefully consider these and then vote as their judgment directs.

Preventive medicine has newly come to American life. It has newly come to most of those who are practicing it. Two years ago there was no instruction leading directly to the position of health officer. Now Harvard and Columbia have courses preparing for such work, Michigan establishes such a department in the fall, and Northwestern and several other universities are giving courses in these subjects for medical men; various colleges of technology are giving courses in sanitary engineering which partially qualify. The School of Civics and Philanthropy gives a course in social science, and the Chicago Health Department, incorporated as the Chicago School of Sanitary Instruction, gives practical work. But, much as this appears, it is but a bagatelle as compared with the large number of physicians newly come to the position of health officer, untrained and untried, and the large number of towns with newly created health departments—like a butterfly newly come from a grub, looking around on a new world and beating a new element with a new organ—new wings. They all want to do what is right. But what is right?

Therefore, we have decided to deliberate on methods of doing things. When we have carefully counseled, we shall vote. Such methods as meet the approval of the Section will be sent to the House of Delegates or to the Council on Health and Public Instruction. The reason for thus referring the Section actions is twofold: First, the By-Laws of the Association prescribe that resolutions cannot be passed by the Sections; second, measures gain prestige by coming from the Association as a whole.

The second part of the plan is this: Prior to and during the meeting there will be a series of health talks for the general public. The American Medical Association is a peculiar organization. Its deliberations have something more to do with human welfare than those of the average organization. Hitherto it has gone to a community and deliberated behind closed doors.

The people of the host city have not seen much of those attending except as they have met them at receptions and lawn parties. That is not right. Why go to the trouble of entertaining four thousand physicians if no lasting good is to come of it? Should we not earn our welcome by conferring a lasting benefit on those who have given of their time and money for our entertainment?

A campaign of public education in southern California was begun last week. It will continue for another week. We trust that many citizens of this vicinity will have learned something new about right living as the result of lectures given by members of this Section and others.

The third part of the plan is a health education exhibit for physicians. Part of it hangs on the walls of the exhibit room and part of it is to be found in the California and Louisiana health cars.

This is the plan for this meeting which your officers have worked out.

You also honored me with an election as orator. As orator I wish to address you on "The Relation of the Medical Practitioner to Health Departments."

ORATION ON STATE MEDICINE

Death represents the passing of the human being from the known into the unknowable. What is life? What is death? Why is death? What after death? All of these are unknowable. The end of life is no more a mystery than its beginning, but the mind of the being at the beginning is too feeble to know or care. At the end it has learned much and yearns for more. It asks many questions. It does not enjoy being baffled. Therefore, everything connected with this mystery takes on attributes of mystery. The man facing death leans on his physician. His imagination clothes that physician with some of the superhuman qualities.

---

* Chairman's Address and Oration on State Medicine before the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

At first he was a god, and then a demigod; then a man, but bewigged and "caned" and separate and oracular; and now he wears a bob-tailed coat, smokes cigarettes and is quite human. The old-style physician was regarded with awe, was given a blind faith and was tenderly loved. *His scientific service was very slight*—but he was good for sickness. His coming brought peace and hope. As the scientific capacity of physicians has become more worthy of faith, they have been given less. And now the old, blind, unreasoning faith has gone and it will never return. The bringing of medicine out into the plain, white light of common day has reduced the death-rates, increased the average age at death, the average length of human life. It has substituted real for psychic benefit. But all of this is working changes which are not fully comprehended by physicians or laity. Why has the old faith died? Several things have operated to bring it about.

Chief of these is the general growth of information. *There was a good deal of humbuggery in the old practice*, and humbuggery has fallen into hard lines everywhere. People are now better informed, and they judge physicians and everything else better than they used to. Wonderful cures made by physicians they know now were spontaneous cures.

Drug-stores have served to break the charm in two ways. More of a spell goes with medicine when the physician ladles it out than when he writes an easily-understood prescription which the druggist dispenses. In the second place, the very matter-of-fact druggist's over-the-counter prescription ends many an ill that formerly added to the miracles of the physician.

Patent medicines and advertising doctors cure many *ills strangely like the ills the physician used to cure.* When a patient hears the physician abuse patent medicines and advertising doctors, that patient's faith in them often dies, but his faith in physicians shrinks a good deal also. Then, too, those advertisements on the wrappers and in the papers, taught us a great deal of the false, but there was here and there a kernel of truth, and the people are learning how to winnow the wheat from the chaff. Learning from this source, abused by physicians, has decreased general faith in physicians.

The fight on homeopathy has served to decrease the old, blind faith. For did not the homeopathic physician's patients recover? And did not the old doctor say there was "nothing in it?" He could not have been infallible.

And then Christian Science has taught the people that if they would just sit still and bear their ills, they would occasionally get in bad holes, but that often they came out all right; and those who came out all right think the physician was not so smart after all. So they pay the "Science" healer all the more jubilantly because of their resentment against the older teachings.

A large part of the old physician's work was nursing work, and then along came trained nurses and did many of those mysterious things as well as, and often very much better than, we remember the man of mystery doing them.

Then the specialist in his highly trained field makes the old-style physician look awkward, inefficient, and very commonplace; the consultant, the very philosophy of whose presence is that he knows more, necessarily makes the patient think that the old-style doctor knows less; the hospital takes the patient from an atmosphere where the family physician is the only tall, strong thing, into an atmosphere of nurses, and other doctors, and comparisons.

It is a sad thing to see some parts of the old pass away, yet it is quite inevitable. Suppose an old-style physician were to determine that he would have no nurses, no hospitals, consultants, specialists or druggists, how long would he hold any patients? The people would lose not only old-style, blind faith, but all faith; he would be discarded, friendless—an outcast. It is inevitable. We can pause to drop a tear, but after this *we must move on.* We must adapt ourselves to the new requirements, being sure that somehow they are for the best.

In the last analysis the thing comes back to this: The people want to be cured, or kept well. It is for them to decide how this is to be done and by whom. What posi*tion toward this change is it wise for the profession to take?* My position is that nothing is gained by opposing the inevitable. Much is lost by opposing it; much is gained by adjusting oneself to it. That which is inevitable for the long run is right for the long run.

Taking it on the average, I do not think physicians make much from treating contagious diseases. Diphtheria now means but two or three visits; and probably a reputation of attending diphtheria scares away more visits than that. The same thing is true, though in lesser measure, of other contagious diseases. Occasionally *a physician carries contagion, or the family thinks he does*; it comes to the same thing. *It costs the practice* of that family at the very least.

Do you think a physician who has a reputation as a hider of contagious disease gains anything in the long run? The number of mothers who are protecting susceptible children is such a great majority that their fear and distrust of a man with this reputation presently constitute a very definite liability.

There is not much money in treating consumption, above all in the old-fashioned way. The patient may *pay for the visits for a few months*, but soon the money is all gone and then the physician gets nothing, and *oftentimes he has to chip in to help out.* But suppose the physician is slow in making his diagnosis or hides it *from the health department, or from the patient or family.* If you have ever stood in the streams in which *the consumptives flow, I need not tell you how violently* they abuse the doctor who deceived. In the long run, *the only money in consumption is for the man who for himself and his patient lives up to the law.*

Suppose we shift the illustration to school inspection. It *is disconcerting to have a child sent home for diphtheria determined by culture when you have told the family it was an ordinary sore throat.* But the case being diphtheria, the school doctor must tell the truth. Averag*ing all the cases, the family physician gains more by standing up to the truth than by resisting.*

Again, *it is quite disconcerting to have a child in one of your families come home with a card saying the tonsils should be removed when you had not so advised*; but the wise thing to do is to agree with the diagnosis when it is right, and remove the tonsils. The fact of the business is, the family gets accustomed to the appearance of the mouth-breather; the family physician is anesthetized by repeated monotonies; nevertheless the child is not well—is not able to study with a high degree of efficiency and needs what is advised. Shall the physician take the position that because there is no immediate danger there is no ultimate need? There is no surer way by which he can ruin his eventual standing with that family. There is no surer way by which he can accomplish his ultimate ruin than by assuming this point of view.

These illustrations might be multiplied indefinitely.

It is axiomatic that nothing which puts a great strain on the community, the family or the individual, brings money to the physician (examples: epidemics of cholera and yellow fever). Wherever industry is paralyzed the few who can pay are more than offset by the demands on time, energy and money from those who cannot pay. Not only is there an increase in bad accounts from those that have the specific diseases, but there is an increase in bad accounts for services rendered in connection with other illnesses. Any completely disabling illness continued for more than three months makes the average man a source of loss to the physician. The physician's best source of income is from the diseases which do not greatly disturb the serenity of the community, the family, the individual. By increasing the percentage of the population who are past 30 years of age, the incomes of doctors are increased, since these are the most profitable patients. By decreasing the death-rates among babies, the physician's revenues are increased.

But it is more profitable to return to the general principles.

The end is the cure and prevention of disease. Every measure and every man is a means to that end. The community is going to look to somebody for its health conservative functions. Health departments are community agencies created by and maintained by the community. Their general reputation for altruism is better than is that of the physician. They are closer to the people. Day by day they become closer. Day by day they do new things for the people. It is the more economic way for the individual; it is in keeping with the broader economies. For all of these reasons health departments are inevitable; they will survive. The people will look to them for health conservation. When they look, shall they find the physicians there in partnership, or shall they find them in antagonism? If the community comes to regard physicians as antagonistic to health departments, do the former gain or lose? There is but one answer which far-seeing would dictate.

There is a general law of society that those who serve are supported. Society starves the useless. If the medical profession is useful, in this inevitable program of society it will be supported; otherwise it will not be. As I see it, the wise thing for the medical profession to do is to get right into and man every great health movement; man health departments, tuberculosis societies, child and infant welfare societies, housing societies, etc. The future of the profession depends on keeping matters so that when the public mind thinks of these things, it automatically thinks of physicians, and not of sociologists or sanitary engineers. The profession cannot afford to have these places occupied by others than medical men. A requisite, therefore, is that there should be places where physicians can get training in sanitation, preventable disease and in hygiene, including housing and ventilation.

This all means a readjustment of medical work. In the readjustment, the revenues of medical men who are giving a low grade of medical service will decrease to almost nothing. Christian Science, hospitals, dispensaries and general intelligence have decreased the revenue of these men until it is now less than that of skilled labor. They have no money for luxuries, nothing for a rainy day, nothing for the proper education and care of their children. Nevertheless, the man who makes his money from superficial home visits must suffer more. Even much of the little that he is now doing will be lost to him in some measure through the care of health department officers, but much more through other agencies. The children who are now going through the schools and who have been going through them for ten years, will establish the practice within the next ten years. Would we not eventually gain by willingly giving to Christian Scientists, counter prescribers and others, all those who can be cured by any form of mental therapy, and concentrating our energies on more worthy fields?

Health department work imperils the existence of certain physicians, in that it tends towards socialism; it tends toward state medicine. The citizen says, "If the state will do these things for me, why should I employ a physician for anything?" Just now hospitals and dispensaries are doing this even more potently. Whatever position against health departments any group of medical men may take, they must take a similar position against hospitals and dispensaries.

Does this mean that all medical work will be taken over by health departments and that private physicians will have nothing to do? There is no disadvantage but some advantage to the physician in this, provided there is a proper regulation of the relation between work to do and men to do the work. But this will not come about in your time or mine. Because people don't rush to physicians for headaches, colds and constipation, some people believe that the rush to physicians has stopped. It has stopped, for that kind of physicians. But a better public intelligence will mean more medical work and more pay to the medical men doing high-grade work.

Perhaps the most illuminating way to look at the matter is to see what effect state education has had on educators. A physician is prone to let his irritation over the loss of a case of contagious disease through enforced hospitalization make him forget the many ways in which that policy, broadly applied, has inured to his benefit. Let us try for a broader view by seeing what has been the effect of enforced state education on teachers. The people are now practically universally educated. The work is done with regard for the broader economies. The number of teachers has multiplied many fold. The pay of teachers has increased; the old academies and private schools and private teachers have nearly all come to an end, but colleges, universities, high schools and grammar schools have replaced them several times over. Is it not reasonable to suppose that the impending and quite inevitable changes in medicine will mean people in better physical condition, work done more economically, more doctors, and especially better doctors?

What is the outlook for better service? One out of every twelve babies dies from birth accident. There should be no deaths from birth accidents. What a field for competent obstetricians! One out of every four babies dies from intestinal disease. None of the babies born on the boulevards or in the better residence districts dies from intestinal disease. What a field for pediatricians! Proper supervision through life prevents the development of heart and kidney disease. What a field for the alert family physician! There is a stage in every case of consumption in which the disease is certainly curable in three months. What a field for the alert internist!

Not one-tenth of the tonsils which should be removed are being removed. What a field for the laryngologist! A large part of our people are working at low efficiency by reason of poor sight. What a field for the ophthalmologist!

The orthopedist and the surgeon could increase the working capacity of a large part of the people if they could get at them. Probably there are not enough surgeons to do all the surgery demanded by considerations of the greatest efficiency, comfort and happiness. And certainly there are not enough dentists to do all the needed dentistry.

These views do not go far into the future. They are right at hand.

I hope I have said enough to prove that nothing is gained by the medical profession by opposing the inevitable—that there is the brightest of futures for the profession and for the individual physicians who recognize the inevitable and properly adjust their methods, their labors and their point of view so as to make the largest use of it.

CONCLUSIONS

1. The best interests of medical men demand that they adapt themselves to the inevitable evolutions in their work and in that of health-governing bodies.
2. The physicians should always take the leadership in health movements in their communities.
3. To offset unnatural prejudices, a campaign to demonstrate that this leadership has broad and altruistic motives must be maintained and all right-thinking people must be brought together in support of the great work of physical welfare.
4. This Section must be so enlarged as to affiliate with it associations of health officers, Young Men's and Young Women's Christian Associations, sociologists, sanitary engineers, school examiners, those interested in child hygiene, infant welfare, milk commissions and tuberculosis associations, ventilating engineers, housing students and school teachers' associations: in a word, all of those bodies that are working for physical welfare. A working plan for cooperation with these should be worked out by this Section of the American Medical Association, so as to prevent duplication.
5. Subsections for some of these should be established in this Section. The constitution and by-laws of the American Medical Association should be so amended as to include such workers for physical welfare as choose to come in.
6. Every county medical society should inaugurate sections to take up different divisions of welfare work and should give modified membership in their societies to all local workers for physical welfare.
7. There should be a health journal or health newspaper maintained by this Association for the purposes of public education on physical welfare.
8. This Section must work closely with the Council on Hygiene and Public Instruction, directing it and receiving direction from it.

Imbeciles as Potential Criminals.—G. A. Auden quotes Fernald (*Jour. Crim. Law and Criminology*) as saying that it cannot be too strongly impressed on our notice that every imbecile, especially the high-grade imbecile, is a potential criminal, needing the proper environment and opportunities for the development and expression of his criminal tendencies. The life history of the imbecile put under permanent protection and training at an early age is very different from that of the feeble-minded who grow up at large in a modern urban community. Nearly all of the imbeciles trained from childhood or youth may be taught habits of industry and comparatively good behavior, and a large proportion of them settle down to a condition of inhibition of the antisocial traits, and indeed to a condition of ostentatious pride in the virtues which they unwillingly practice.

SOME DIFFICULTIES ENCOUNTERED IN THE THERAPEUTIC USE OF TUBERCULIN *

FRANCIS M. POTTENGER, A.M., M.D., LL.D.
MONROVIA, CAL.

That the intelligent employment of tuberculin in the treatment of tuberculosis is attended with excellent results, is now almost universally admitted. To be sure, there are still some who are unconvinced. Absolute unanimity of opinion, however, has rarely been attained in medicine, and we are not expecting it in this instance.

Tuberculin is by no means an easy remedy to administer. It requires much careful study and close observation to be able to use it to best advantage. The proper administration requires the giving of the right dose at the right time. To administer the right dose at the right time requires judgment born of experience; for it cannot be determined by rule. Tuberculin treatment is not what it is often supposed to be: merely the introduction of a certain number of drops of a certain dilution of tuberculin into the body tissues by means of a hypodermic syringe, and repeating it at certain intervals according to rule. If this is all there is in tuberculin treatment it might as well be turned over to a nurse or to the patient for self-administration.

Tuberculin can produce a varying degree of good results, also a varying degree of harmful results, according to the method of its administration. Its proper administration can be carried out only when the physician has an intelligent idea of the nature of the remedy and its action and when he has made a careful study of tuberculosis, both as to its clinical course and its pathology. This should be self-evident; yet it is disregarded in practice, if we are to judge from the manner in which it is often employed to-day. It is often administered as though it were an indifferent remedy and as though tuberculosis were a disease of no seriousness.

The dosage of tuberculin is modified by many influences, such as individual susceptibility, the character and location of the lesion, whether it is extensive or circumscribed, active or quiescent, according to the conditions under which the patient is being treated, whether in an institution or in ambulatory practice; whether he is resting or working; according to the accompanying complications and conditions, such as colds, influenza, bronchitis, hemorrhage, menstruation; also according to the preparation employed. There can be no set rule. The man who understands this remedy individualizes and aims at the production of results. He forgets stated intervals, and rules for increase of dosage and is guided entirely by the effect obtained. A hypodermic syringe filled with tuberculin cannot cure tuberculosis. It requires an intelligent brain to guide it.

Having had the honor of being one of the pioneers in the therapeutic employment of tuberculin and for several years having been one of the largest users of it in our profession, I have been consulted personally by many physicians, and others have written me for instructions how to use it and have related their difficulties and asked my aid in overcoming them. From my own experience and from the experience of these physicians, I hope I may be able to steer others clear of some of the difficulties that are encountered in this line of therapy.

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Unfortunately, those who use tuberculin most intelligently are divided into two camps, those who believe in using progressively larger and larger doses, suiting the dose to the patient and the pathologic process, and spacing the dose according to its size and the conditions present; and those who believe in the repeated small doses given at stated intervals. Between these two camps there are many stragglers who, without any particular ideas, are following no rule, but simply injecting tuberculin and trusting to the Lord to take care of the patient.

I have given both the repeated small doses and increasingly large doses a fair trial and found that I can, in most instances, produce best results by the progressively increasing dosage; and, this is what we should expect from a theoretical consideration of the action of the remedy. Tuberculin produces its beneficial effects in two ways; first, by stimulating the machinery of immunization to the production of more antibodies; and second, by causing a local hyperemia about the focus of infection which enables the antibodies to be applied more directly to the bacilli and which also stimulates the cells to the formation of fibrous tissue about the diseased foci. Examinations of the blood show that the agglutinins and other antibodies are produced in greater amounts after the larger doses although both large and small doses will increase the immune content of the blood. The treatment of local tuberculous ulcers shows that repeated small doses fail to produce hyperemia and that the progressively larger doses are necessary in order to maintain it about the focus of infection. Experience also shows that a condition of hypersensibility is more apt to occur when the small dose, administered at infrequent intervals, is employed. This is a very unfortunate condition from the standpoint of therapy and one which makes further use of tuberculin very difficult.

Whether or not hypersensibility will develop depends very largely, according to my observations, on getting the patient started right. It is a well-established principle in experimental immunization that small doses of protein cause a hypersensibility to further doses of the same protein, while larger doses cause an immunity to it. The time between doses is also an important factor. The space of time between the first few doses of tuberculin should not be long. Many men, who are unaware of these principles, in their attempt to be extremely cautious, give an initial minute dose and then delay for a number of days before giving another. This is not conservatism, it is error; and it shows a failure to comprehend the principles of immunity. The only conservatism in tuberculin therapy is the employment of the proper dose both as to size and time. No matter what preparation I use, I begin with a dose that I feel will not produce symptoms. This dose is determined by the condition of the patient and the nature of the lesion. I use a smaller dose in an active case than in a quiescent one, and in an early case than an advanced one. I also use a smaller dose in a young child than I do in an adult; in a nervous patient than in a phlegmatic patient; also when the infection involves a delicate organ such as the eye in contrast with the involvement in the lung. After the initial dose has been given I proceed with short intervals between doses, one day usually between the first and second, and one or two days between the second and third and two or three between the third and fourth, according to the patient, the lesion, the effect of the preceding dose and the preparation employed. I increase the dose rapidly, making each successive dose two, five or ten times the preceding one, according to the remedy and conditions present, until four or five doses have been given. After that I am guided entirely by my opinion of the case and the manner in which the patient reacts to the remedy. This method has proved very satisfactory inasmuch as it almost guarantees freedom from hypersensibility and troublesome reactions. I have not had a case of pronounced hypersensibility develop among my patients for the past four years. With my method of further carrying on the treatment, which consists in making each successive dose depend on the action of the preceding one, a temperature reaction of more than a fraction of a degree is almost unknown in my practice. Each dose of tuberculin is followed by what might be called a period of increased immunity or decreased sensibility to the remedy. The length of this period varies according to the dose employed; and the time of its appearance depends on the size of the dose, appearing later and lasting longer after large doses than after small ones. Within this period it is safe to repeat or increase the dose. Earlier will almost surely produce a reaction and later is apt to do so, especially if the dose is increased. An appreciation of this fact will greatly facilitate the employment of tuberculin.

The length of time that a patient should be treated with large doses of tuberculin is a very important question. After a large dose has been attained should this dose be repeated time after time? I am of the opinion that, as a rule, it should not. I am guided in this, however, by the character of the process. I use repeated large doses for a time in incipient or chronic inactive cases; but rarely in active, especially chronic active ones. I have found it best to have at my command several preparations of tuberculin. I usually run up to a high dosage on one and then drop back to the initial dose of another preparation and gradually work up again. This method has several advantages which commend it. In the first place, different preparations act somewhat differently and it is well to give the patient the benefit of their different actions. Again—and this I deem very important—it is not well to keep up a maximum focal stimulation such as is caused by the larger doses, for a long time. It has been shown, as mentioned above, that both large and small doses stimulate the machinery of immunization to the formation of antibodies; and that the larger doses cause the more pronounced focal reactions. Therefore, I deem it wise to carry my patient up to a large dose, and then if the case is an incipient one or a chronic inactive one, repeat it several times before changing to another preparation; but, if it is an active case, especially a chronic active one, not to repeat it, or at least not more than once or twice. The term "large dose" must be considered relative. A large dose for one patient is a small dose for another. I mean by a large dose, the one which my judgment tells me is large for the given patient, although I have never found it necessary to exceed the limit of dosage as usually laid down for the various preparations.

One of the greatest difficulties in the therapeutic administration of tuberculin, granting that one understands the pathology of tuberculosis, the nature and theory of the action of tuberculin and is capable of making a fairly accurate examination of the chest, is to be able to intelligently interpret the temperature curve of the patient. There are varied causes for the general temperature curves and so many factors which enter into the daily variations in the curve that one is often at a complete loss to interpret them. It is essential to know first that the curve of the tuberculous temperature is not uniform. It runs in waves. It is up for a time and then down for a time until the patient finally attains an arrest in the activity of the disease. It shows this same character whether the patient is taking tuberculin or not. The curve is modified by physical exertion, the mental state of the patient, the condition of the digestive system, atmospheric changes, complications and many other conditions. Unless this is understood it is impossible to carry out tuberculin treatment intelligently except in cases absolutely free from fever. Some physicians take each of these rises in temperature for auto-inoculations; others think that every time the temperature rises it is due to the tuberculin used therapeutically. Such interpretations prevent the proper administration of tuberculin and are based on error. It is necessary to be cautious, but unless one is careful to inquire into the causes of these temporary variations in the temperature curve and to assign to them their rightful causes, or at least not to allow them to interfere with the proper increase and spacing of dosage, no progress can be made at all in the therapeutic application of tuberculin to a given patient. Patients are sure to have rises in temperature every now and then from some of the innumerable causes mentioned above. When doses of tuberculin are being given every second to fifth or sixth day, the probabilities are that some of these rises will come on the day of the dose. It is most natural, under the circumstances, to interpret them wrongly as being caused by the remedy. Unless one recognizes this probability and uses care in his interpretation, he cannot use tuberculin to advantage. I am positive that in our endeavor to be cautious we often ascribe to tuberculin many rises in temperature that are not due to it at all.

This brings us to the discussion of the question as to whether or not tuberculin should be used therapeutically when fever is present. My extended experience in the use of the remedy permits me to say that tuberculin is of decided advantage to the patient suffering from fever. I am not unmindful of the fact, however, that fever patients are extremely difficult to treat and that they should not be treated except by those who are thoroughly conversant with tuberculin and its therapeutic employment. The variations in the temperature curve of fever patients are much more difficult to interpret than those in the usual non-febrile patients.

The action of tuberculin is to increase the patient's immune bodies and to favor healing by causing a local hyperemia about the focus of infection as mentioned above. Tuberculosis has a constant tendency to spread; in fact, this is the factor about it which destroys the patient. At no time is it more apt to spread than when the patient is suffering from fever, when activity is present and the tissues are breaking down. If there is ever a time when the tissues should be fortified and the body fluids should be surcharged with antibodies in order to save the patient, it is while this is occurring.

The objections raised against its use during fever are not well founded. They are based on a supposition that the fever is an indication that tuberculin is already circulating in the tissues in large amounts; but this is not true. As mentioned elsewhere,[1] if it were true, all local tuberculous ulcers would show constant reaction during fever, which they do not; and as a result of the constant focal reaction the tissues would break down and we should have a generalized softening of all tuberculous foci whenever a chronic temperature exists, which also does not occur. Further evidence of the fact that the body is not surcharged with tuberculin is afforded by the observation that visible tuberculous foci which do not show reactions even when fever is present can be made to react promptly by the administration of tuberculin.

Thus we see that the necessity for the administration of tuberculin is even greater when fever is present than when it is not present; and that the supposed argument which has been put forth as a contra-indication is not valid. To be sure, skill is required to treat patients with fever; but it is certainly gratifying to see portions of lungs clear and tuberculous complications improve while the fever is present; and see these patients come out of a siege of fever which has lasted for weeks or even months without the disease having spread to new tissues and with tissues which have been primarily involved cleared up. The disappointments in the results of tuberculin treatment which I have heard expressed by physicians seem to be due to three causes: faulty technic, a failure to recognize the limitations of tuberculin, and an inability to observe the beneficial changes which the remedy produces with sufficient accuracy.

I have already discussed the more important errors in technic although I have not mentioned the many little details such as those connected with making dilutions, cleansing the syringe, measuring out the dose, and administering it, that contribute so much to successful therapy, and which, when disregarded, mean almost certain failure. These, while very important, are too elementary for discussion at this time.

It is as important to know what a remedy cannot do as to know what it can do. If the limitations of tuberculin were thoroughly understood much disappointment would be avoided. That tuberculosis, after it extends beyond the initial stage, is always a complex condition, should always be borne in mind.

Tuberculin has only a specific action against the tubercle bacillus and its toxins. It cannot cure mixed infection nor can it prevent the deleterious effects resulting from enzymes and the products of their action. It can aid in the healing of tuberculosis; but it cannot be expected to exert a specific action on necrotic tissue. It cannot cure consumption although it can aid in curing the more recent lesions even in advanced cases, and it can aid in keeping the blood reinforced with antibodies, thus helping to prevent the disease from spreading. It cannot restore tissue when once destroyed, nor can it overcome the effects produced by the disease. Yet all of these impossible things seem to be expected of it.

Much of the value of tuberculin cannot be observed. We cannot see its action in stimulating the machinery of immunization and protecting the body from new infections occurring from the bacilli which escape from old foci. Unless examinations are made far more carefully than usual we cannot determine the healing of the areas of slighter infections in the lung. The changes are slow, as can readily be seen by the fact that it requires on an average six months for an early case of tuberculosis to heal. Only the most careful expert examinations can determine the changes which occur from month to month. Unfortunately few men have been schooled in making examinations with sufficient accuracy to be able to determine this; consequently, it is necessary in the treatment of this disease to take a great deal by faith. Physicians must not expect great changes to occur in a short time, but must be patient and remember that the changes which would occur in an ordinary acute illness in a few days or few weeks require many weeks or many months in this disease.

ABSTRACT OF DISCUSSION

DR. WALTER BREM, Los Angeles: Von Pirquet in his recent article on "Allergy" in the *Archives of Internal Medicine* has discussed the subject of reactivity to tuberculin; he thinks that altered reactivity of the tissues to tuberculin is due to the presence of antibodies, which so act on tuberculin as to convert it into a toxic body. When an apparent tolerance for tuberculin is developed by the administration of gradually increased doses, von Pirquet thinks that what takes place is a decrease in the number of antibodies. If that view is correct, I think that one should be very careful how one creates this apparent tolerance for tuberculin, and that it would be desirable to graduate therapeutic doses according to the degree of reactivity so that the reactivity would not be altered by a decrease of the naturally developed antibodies. White of Pittsburgh has introduced a method of graduating doses of tuberculin by which he thinks that he can avoid altering naturally developed reactivity. He finds first the quantity of tuberculin that in the cutaneous test will produce a "minimal reaction," a papule 4 to 6 mm. in diameter, and then he injects that quantity subcutaneously. If, for example, .01 c.c. of a 1 per cent. solution (O. T.) produces a papule 4 mm. in diameter, then he uses an equal quantity, 0.1 mg., for the subcutaneous dose. By using a careful technic in his cutaneous test he finds a definite quantitative relation between the skin reaction and the reactivity when tested subcutaneously. A dose producing in the cutaneous test a papule 4 mm. in diameter will, when given subcutaneously, produce an area of redness 4 to 6 cm. in diameter, and such a dose never produces any general reaction. Furthermore, if the doses are spaced ten days apart no alteration of the naturally acquired reactivity is brought about. White's method is interesting in connection with the theoretical considerations of von Pirquet. The object aimed at by White is logical if von Pirquet's ideas are correct. In view of this and also in view of the fact that White has reported excellent results from the use of his method, it seems to me that the method is worthy of careful trial.

DR. JOHN RITTER, Chicago: Using tuberculin daily in practice in ambulatory cases I am very much impressed with what Dr. Pottenger has told us just now and feel assured that tuberculin finds its best application in the sanatorium. Ambulatory cases will not give such good results. Tuberculin is a double-edged sword. Tuberculin should only be used by those who are familiar with it. The more I use tuberculin the more I am convinced that it should be used in the sanatorium and only to a limited extent in ambulatory cases. One cannot watch ambulatory patients as closely as those in a sanatorium. The average physician looks on tuberculin as a specific. Tuberculin is a specific only in effect. It is not a specific in the degree that mercury is a specific in syphilis, but we get definite results in tuberculosis with tuberculin. It is not a curative measure, it only assists us in the cure of tuberculosis. This paper by Dr. Pottenger should be taken home and read again and again and then tuberculin should be used only when the practitioner is familiar with the cases, or he should send them to a sanatarium where they will be under careful observation at all times.

DR. EDWARD VON ADELUNG, Oakland, Cal.: Probably our principal interest centers on the question which covers the whole discussion, namely, Is tuberculin of value at all? We all know that some people do not feel that tuberculin is of any value, but I hasten to add that I am on Dr. Pottenger's side in feeling that tuberculin is a valuable addition to the usual hygienic, dietetic and climatic treatment of this disease. There was a time when I was in doubt. I was convinced only by clinical evidence, not by theoretical explanations. By clinical experience I do not refer alone to my own experience, which was of some satisfaction, but to the reports of men like Bonney, Trudeau, Baldwin, Pottenger and a number of men on the other side of the Atlantic, who stated that they had given patients the benefit of all treatment without tuberculin, had seen them attain a stationary degree of improvement and had then found that by giving tuberculin in addition, further improvement was obtained. This to my mind was convincing. We are pretty well convinced that when we cure tuberculosis we do it through cell resistance to the bacillus and its toxins. Hygiene and diet do it in that way. Tuberculin acts in the same way. In our attempt to measure the action of tuberculin we seized on Wright's demonstration as a gauge; but we found it to be inadequate. We have fallen back on the clinical valuation and we still rely on this method of gauging our treatment. We cannot state with mathematical accuracy the proper dosage or the number of days between doses. But as well pointed out by Dr. Pottenger these are matters of individualization and cannot be argued out. I should congratulate Dr. Pottenger when he says that he no longer—or exceedingly rarely—gets reactions. Here our experiences have differed somewhat. I find from what he says to-day that I am using tuberculin in practically the same way as he is, except that I try to find the maximum dose of tuberculin that I can give to each individual at fixed intervals of time, the theory being that I am using a stimulant to tissue resistance, just as we use strychnin, or digitalis, or atropin in appropriate conditions, realizing that we use these stimulants within their physiologic limits. And so I have been using tuberculin to the physiologic limit. I sometimes get a reaction; rarely a reaction of any importance; usually very slight. Then I know that I have reached, at least for some weeks, my limit of dosage for that patient. I have also found, as has Dr. Pottenger, that a change of brand of tuberculin is of value, the stimulation on changing is noticeable. The use of tuberculin during fever is a field that I have not trodden on. I have usually regarded a continued fever in tuberculosis as the result of a toxin and supposedly the toxin from the tubercle bacillus, or tuberculin, and hence contraindicating the use of tuberculin. I do recall now one patient with fever, who appeared to me to be fully saturated with toxin, whom I agreed to treat with tuberculin only at his pleading—an indigent who had been sent to the county hospital and came back and begged me, in a moribund condition, as I thought, to give him tuberculin. I did. His is one case which has opened my eyes to the fact that many hopeless-appearing patients can be helped. This man improved in many ways, including weight, appetite and strength and is now walking about the streets and earning a living. He had no treatment other than hygienic and dietetic, except the addition of tuberculin. I presume that bears out the contention that tuberculin has its use in fever conditions.

DR. W. C. VOORSANGER, San Francisco: I would like Dr. Pottenger to explain his position on the prophylaxis of tuberculosis and how far it may be effected by tuberculin therapy, i. e., tuberculin injections. By that I mean that, supposing a case of tuberculosis in the prebacillary stage, if you like, or supposing a case in which we only have the bronchial glands tuberculous—a glandular tuberculosis in which there are no actual symptoms—I would like to know exactly his position in the administration of tuberculin in these cases and how long he would give tuberculin and at what stage he would stop. In regard to the injection of tuberculin, I believe that the great difficulty which most people experience is that they are looking for an immediate, definite result and I do not believe it can be had. When one administers digitalis in a case of cardiac trouble, if the pulse is about normal and the patient about well, one does not go on administering digitalis two or three years longer. If the patient has another break in compensation, one administers digitalis again. I believe one should look for the symptomatic result. Dr. von Adelung spoke of using tuberculin up to its physiologic dose. I do not exactly understand what is meant by that. I do not believe we should use tuberculin any further than the patient can tolerate it, and that when we receive a symptomatic result from a dose, and the patient is doing well, then that dose should be maximum. I do not believe the same maximum dose for every patient is possible. In starting I use 1/20,000 mg. of bovine tuberculin. I always start with that and I have no maximum. When, after several months, a patient is doing well on a certain dose, this should be the maximum dose. I never could see any reason for increasing a dose to a definite maximum. I believe that each patient should have a different maximum. When the patient reaches the point where he can tolerate a certain dose of tuberculin, and do well, that should be the place to stop. In other words, one must individualize with tuberculous patients in the same manner as with patients afflicted with any other disease.

Dr. Charles O. Probst, Columbus, O.: I wish to emphasize the danger of improper use of tuberculin. A large producer of tuberculin, a physician, a skilled bacteriologist, a tuberculous subject who has taken tuberculin in its treatment, told me that it was with a great deal of trepidation that he placed it on the general market. He feared that if used widely it might do more harm than good. For the average physician, and especially those who have not had laboratory training, the mere making up of dilutions is a matter of difficulty. To meet that the producers are sending out doses in serials to be taken so many days apart. If what Dr. Pottenger tells us is correct as to the great care needed in the administration of tuberculin, I can see some danger in putting up tuberculin in that shape for the use of the general practitioner.

Dr. Max Rothschild, San Francisco: The necessity of individualizing in every case is undoubtedly of the greatest importance and I am in harmony with Dr. Hare in condemning the houses which put tuberculin on the market in serial dilutions and induce the general practitioner to treat tuberculosis according to a schedule. In regard to the treatment of fever I must say that I take a different standpoint from Dr. Pottenger. Before I try to give my patients, who have fever, tuberculin, I always put them to bed for at least four to six weeks and see if the fever does not go down with absolute rest in bed. It usually does and I have found that if the fever does not disappear with the absolute rest in bed after four to six weeks it very rarely disappears under the tuberculin treatment. The question whether it is always better to send patients with tuberculosis to sanatoriums is difficult to decide, and a very important one. There is no doubt that the patient who can afford it should go to a sanatorium, but there are hundreds of poor patients who haven't the money to do this, and the public institutions for the special treatment of tuberculosis are so few that only a small number of the tuberculous poor can be accommodated. Now, what is going to become of these? Are they going to be deprived of a treatment which most of us consider a very important one, and one which might save their lives? In a paper which I read about a year ago in Nevada, at the state medical meeting, I took up this point. I believe that every practitioner should learn how to use tuberculin. A good physician knows how to treat a difficult case of pneumonia and he knows how to treat a difficult case of typhoid fever. These diseases, like many others, need a good deal of knowledge and circumspection in order to be treated properly and successfully. Now, why should a general practitioner, who knows how to treat such other diseases well and correctly, not learn how to use tuberculin? It should be made a part of the physician's education, so many a poor tuberculous patient could be properly treated and perhaps saved, whose circumstances would make it otherwise impossible for him to receive the benefits of the tuberculin treatment in a sanatorium.

Dr. J. S. Trewhella, Los Angeles: Should we simply increase the dose of tuberculin until we get the reaction? What are the symptoms from a minimum reaction?

Dr. J. E. Pottenger, Monrovia, Cal.: I would like to speak of the possible value of the laboratory in aiding in the interpretation of temperature. As there is always more or less intoxication from stomach and bowel disturbance in these cases its detection by laboratory methods may aid in the interpretation of the temperature curve.

Recently I had two patients one of whom, with a very irregular temperature, was known to have considerable disturbance of this kind. The other was undergoing an acute extension of the disease in the lung, with atypical temperature. From daily twenty-four-hour quantities of urine the indican was determined quantitatively. From twenty-four-hour specimens of sputum the total amount of solid material was determined. White blood-counts were made each day. In the first case I found that the maximum indican elimination corresponded fairly with the rise in temperature, while the blood-counts and solid matter in the sputum remained approximately the same. In the second case there was a pronounced increase in the amount of solid matter in the sputum, while the indican and white blood-cells remained practically the same. The conclusion was that in the first case we were dealing largely with an atypical temperature due to intestinal intoxication. Such data may aid in clearing up doubt as to the effects of our tuberculin inoculations.

Dr. Mazyck P. Ravenel, Madison, Wis.: While agreeing heartily with what Dr. Probst has said, I wish to put in a plea for the commercial houses that put out those serial dilutions of tuberculin. We all recognize the dangers of careless or faulty dosage, and these houses are giving to the physician accurately measured doses. Dr. Lawrason Brown, who has had about the largest experience in the United States, has published a table of dilutions, and only the other day Dr. Kress of Los Angeles published a similar table in The Journal of the American Medical Association (April 29, 1911). I presume there are very few men in the United States who have made more tuberculin than myself, and yet to this day I never make dilutions without realizing that I have an exacting and difficult job on hand. Those firms that are putting out the serial dilutions are putting into the hands of the general practitioner the proper dosage, properly prepared and in an absolutely safe way.

The man who does not know when he is giving the wrong dose and does not recognize hypersensibility, has no business fooling with tuberculin at all. To condemn tuberculin because some men give it wrongly is as unfair as to condemn strychnin and morphin because poisonous doses are sometimes given.

Dr. Robert A. Peers, Colfax, Cal.: Serial dilutions commence with too high a dose. No. 1 in all serial dilutions contains 0.01 part to the cubic centimeter; the commencing dose should be 0.001. I have had prepared three dilutions, one in which there is 0.001 to a cubic centimeter, one in which there is 0.0001 and one in which there is 0.00001 to the cubic centimeter, and then I commence either with a 0.00001 mg., which would be a tenth of 0.0001, or else I give 0.000001 as the commencing dose. I believe there are some who start with smaller doses than that, but I think it is wrong for anyone who is using tuberculin to commence in all cases with serial dilution No. 1, because they will find that they will get a great many reactions. I am not sure that I understood completely Dr. Pottenger's attitude in regard to the administration of tuberculin in patients with fever. For two years I have not been giving tuberculin to patients with elevated temperature, except in rare instances. I do not believe that any man should advocate the use of tuberculin in patients with a temperature above 100 F. In patients who are running a temperature of between 99 and 100 F. I think there is good ground for its use in so far as we know about tuberculin. I believe we know very little about tuberculin yet. I believe very much in the use of tuberculin. If I had tuberculosis myself and was not running a temperature I would want tuberculin used and I would want somebody to use it who had experience in it. Perhaps Dr. Pottenger does not advocate it in temperatures above 100 F.; but if he does advocate it he cannot impress too strongly on the members of the profession that they must use the greatest caution in using it.

Dr. Gerald B. Webb, Colorado Springs, Colo.: I am a great believer in the value of tuberculin. I perhaps use smaller amounts. While listening to this discussion I wondered if Bernard Shaw had been present at a similar one before writing his "Doctor's Dilemma." Before antitoxin was introduced the treatment of diphtheria covered many pages in the text-books. It is evident from the discussions that we have no specific yet for tuberculosis. Tuberculin, after all, is a preparation of dead germs and little immunity can be obtained in tuberculosis without the use of the living germ. At the International Congress on Tuberculosis, 1908, I suggested a method of inoculating the living germ. I have had some fifty volunteers up to date. I have done no harm and I have felt the results were better than with tuberculin. I have fully satisfied myself as to its safety on guinea-pigs, rabbits and monkeys. The inoculation of the living germ frequently brings down the temperature, as Dr. Pottenger has found with tuberculin. Practically the whole human race becomes infected with the tubercle bacilli and I believe we can prevent this infection to a large degree by the inoculation of the living tubercle bacillus. We have been able to inoculate young monkeys with safety with enough virulent human tubercle bacilli to kill 20,000 guinea-pigs. By this method I have already safely inoculated two children.

Dr. F. M. Pottenger, Monrovia, Cal.: According to von Pirquet, as suggested by Dr. Brem, when large doses of tuberculin are administered, the antibodies should all be used up and the skin test should prove negative. I have tested numbers of patients who were receiving large doses of tuberculin and they reacted positively without exception. We must not let theory take the place of clinical observation. Whoever administers tuberculin should know the definite quantity of tuberculin in each dose, instead of so many drops of such and such a dilution. No man has any more right to undertake the use of tuberculin without first studying tuberculin and tuberculosis than he has to do major surgery without first studying his anatomy and witnessing operations. While the sanatorium offers the best conditions for the use of tuberculin, I do not agree with Dr. Ritter that it should be used only in sanatoriums. I treat many poor people in my city offices, who are compelled to work while getting well. My results are not so good as those in the sanatorium and the time of treatment is greatly prolonged, yet I am saving many patients who could otherwise not be saved. Those who are using tuberculin intelligently and not expecting it to remove all the results of consumption, put in new lungs, remove cavities and restore hearts and stomachs that have been injured, but who are expecting it to fortify the body against the spread of the disease and help rid the body of pure tuberculous foci; those who are administering it, not by so many drops of this or that dilution once a week, or once in two weeks, regardless of the condition of the patient, but by giving the right dose at the right time, are unanimous in their opinion that tuberculin is of value. The cure of tuberculosis depends on specific stimulation, on the one hand, and the reaction of the body cells on the other; consequently tuberculin should be reinforced by every known measure that will build up the patient and improve his resisting power. Clinical observations are ample for measuring dosage. The early signs of reaction will be detected long before the point of fever reaction is reached. Nervousness, depression, malaise, aching, increased cough and expectoration, nearly always occur on doses short of those which will produce fever. I would not recommend the wholesale use of tuberculin in fever by any means, but I would recommend that those who know tuberculosis and who understand fully the use of tuberculin, try it in fever cases.

Regarding the treatment of tuberculosis before the bacillary stage, as suggested by Dr. Voorsanger, I believe the future cure of tuberculosis is going to be the treatment of infected children. It is wrong to allow these early unhealed infections to become clinical tuberculosis.

As has been suggested I am of the opinion that there should be some man in every community who is capable of using tuberculin in the treatment of tuberculosis. The men who only have one or two patients a year to treat should not think of employing it. They do not have sufficient experience to use it correctly.

My experience with fever cases is different from Dr. Rothschild's. Unfortunately I do not find that the temperature is reduced in five or six weeks. The pathology of these cases makes it impossible for the fever to be of short duration. Very often I find that I can hasten the fall in temperature by tuberculin.

I congratulate Dr. Webb on his most valuable and interesting contribution on immunity in tuberculosis. To my mind he has struck the natural process that goes on in the child from the time of his birth.

Epilepsy.—Celsus, in describing epilepsy, used a term which became immortal. He called it "morbus major." The French translated this into their own inimitable language and gave a name which is to-day the common description of the condition *grand mal*, because the disease was terrifying and great and grand.—E. L. Hunt in *Medical Record.*

THE PRODUCTION OF IMMUNITY IN TUBERCULOSIS BY INTRAVENOUS INJECTIONS OF TUBERCULIN *

C. A. SHEPARD, M.D.
NEEDLES, CAL.

In the treatment of no other disease have there been such strides made in the past few years as in that of tuberculosis. From time immemorial this disease has attracted the best attention of the medical profession, and various have been the remedies and measures proposed for the alleviation and cure of the great white plague, which at the present time is depopulating this good old world of ours at the rate of 1,000,000 a year, and causing a loss to the nation of many millions in money.

Immunity against any disease is based on the fact that the body in the presence of infection and its products has the power to elaborate specific substances—antibodies—that neutralize the toxic microbic product, and promote the destruction of the infectious organisms. We are all familiar with the natural immunity produced after certain diseases, such as small-pox, scarlet fever, yellow fever, cholera, and so on. Metchnikoff says that the persistence of immunity that develops after infectious diseases is due to a permanent increase in the phagocytic power of leukocytes. According to Ehrlich's side-chain theory, which has been adopted as the best explanation of the manner in which immunity and the changes in the cells are produced, toxins are harmful only when they are able to unite chemically with certain cellular bodies—receptors; otherwise the cells are immune to the action of the toxins; that is, when this union cannot take place.

Antibodies in the blood are protective and curative because they unite with the haptophore group of the toxic molecule, and thus prevent the latter from uniting with cells and causing morbid changes in structures and functions (Ludvig Hektoen).[1] The great majority of mankind must have in some degree a natural immunity against tuberculosis. If it were not so the race would long ago have become extinct, for statistics show that 20 per cent. of all adults die of this disease, and 70 to 90 per cent. of all autopsies show evidences of healed or healing tuberculous foci. Our aim in the treatment of the disease is to reproduce this immunity in those cases in which Nature seems to have failed. When tuberculin was first put on the market by Koch it was hailed as a specific, was used in all stages of the disease and by inexperienced men, which was against his advice; with the inevitable result, as in the case of all so-called specifics, that it received a set-back that will take years to overcome. Owing to the careful investigations and experiments of some of the ablest members of our profession, interest has been revived in tuberculin therapy, and at the present time it is receiving a great deal of attention as an aid in the production of immunity in tuberculosis.

Judging from the results obtained up to the present time, there is apparently little difference between the actions of the various tuberculins when properly given, as all probably contain the specific proteid, the chemistry of which is still unknown. Some observers report beneficial results with the Old Tuberculin, some with the Bacillen Emulsion, and others with the watery extract. As Trudeau of Saranac Lake has pointed out, it is not the kind of tuberculin that counts, as much as it is the physician giving it; therefore the personal equation of the physician becomes a highly important factor. Sahli lays proper stress on this point when he says: "The qualifications of the physician who administers it are certainly of more importance in most cases than the kind of tuberculin."

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Hektoen, Ludvig: General Principles of Serum Therapy in Practical Treatment by Musser and Kelly.

The outcome of all the work done so far along these lines has been to establish the fact that tuberculins and their products are valuable aids in the production of immunity in tuberculous lesions. The earlier investigators attributed the curative action of tuberculin to the formation of agglutinins, and similar protective substances, by the cells of the tuberculous when stimulated by tuberculin.

Von Pirquet[2] states that the tuberculin reaction is dependent on the presence of antibodies. In a person who has no antibodies no reaction can be elicited; therefore normal individuals do not react. Neither do individuals in advanced stages of tuberculosis, for the reason that their antibodies have been used up in the fight of the body against the disease.

Hamburger[3] points out that tuberculosis is acquired almost wholly in infancy and early childhood, and that, therefore, adults either are suffering from tuberculosis acquired in early childhood or possess a latent focus which renders them immune to a further infection. The prophylactic employment of tuberculin in infancy and childhood, therefore, should constitute one of its most valuable uses, considering the fearful death-roll caused by this disease among the little ones.

Maragliano[4] says that "Tubercle bacilli, living or dead, are able by their toxins to produce in the organism, specific protective bodies, antitoxins, lysins, bacteriolytic substances and agglutinins. The production of these protective bodies can be brought about by the introduction of tuberculin into the patient."

Trudeau says: "The production of tuberculin-immunity is capable of favorably influencing the course of chronic tuberculosis, of prolonging life, and in many cases of aborting a commencing infection, or extinguishing the smoldering fires of a chronic infection."

Sahli (1896) believes that tuberculin is not merely a specific, but like digitalis in cardiac disease, is a functional therapeutic means, which acts in a definite way on the toxin-susceptibility of the organism. In the ordinary course of the disease, tuberculin is formed so gradually in the patient's system that the organism is rarely stimulated to the formation of any antibodies. In the tuberculin treatment a large amount is thrown into the circulation at once, and so permits the bacteriolytic properties of the tissues to exert themselves—it permits an auto-immunization to take place. Now, if the dose injected is too large, the cells are so affected, with a body already overloaded with toxins, that they can no longer respond to stimulation, and this explains the failure of many patients in advanced stages to react to tuberculin.

Leukocytosis takes place in almost every disease of bacterial origin except tuberculosis. Metchnikoff, in his work on the phagocytic action of the white cells, concluded that these bodies played the part of an armed force, ready to combat any invasion. Buchner followed with the observation that the blood-serum, exclusive of the cellular elements, could destroy disease germs. Finally Vaughan of Ann Arbor announced that by the administration of substances containing nucleinic acid, the number and activity of the leukocytes could be increased.

Having, I think, fully explained that the protective substances which cause immunity can be produced by the injection of tuberculin, and are aided by the administration of other remedies that increase leukocytosis, I shall briefly compare the various methods of administration.

The subcutaneous method is the one commonly used by the profession, and at the different sanatoriums at the present time. I cannot see that it has any advantages when compared with the intravenous method. It is slower in action, painful to the majority of patients, and is often the cause of the production of local abscesses.

The intraperitoneal method has been used by some, and Maragliano has used an intrapulmonary method with some benefit. Tuberculin has also been used by the mouth, with doubtful results, some observers stating that antitoxic serum cannot be absorbed from any intact mucous membrane, and others to the contrary, that a child can be rendered immune by feeding it the products of the tubercle bacilli. I have had no experience with these methods, having used the subcutaneous, and, for the past three years, only the intravenous. Koch, Denys and Rothschild have used and advocated the intravenous method for years, but the advantages of this method over all others have not received the attention they deserve. It is absolutely painless, avoids the danger of abscess formation, allows the use of smaller doses, and gives quicker results than by any other method. It is being used in this way by Dr. Max Rothschild at the California Sanatorium at Belmont, Cal., and at the Cottage Sanatorium at Needles, and with marked success at each institution.

Ludvig Hektoen[1] says:

> The fact that intravenous injections immediately give a far greater concentration of antibody in the blood, and hence in the lymph also, than is ever obtained by the gradual absorption from the subcutaneous tissue, is a strong point in favor of direct injection into the blood. . . . According to Berghard, the curative value of antidiphtheritic serum for guinea-pigs on direct injection into the blood, is 500 times greater than on subcutaneous injection, and so far no dangerous symptoms have developed from these intravenous injections.

Also, further, in the same article, Hektoen, quoting Friedberger and Doermer, says: "Small quantities of bacteria may cause a greater output of specific antibody on intravenous than on subcutaneous injection."

As an experiment I took six guinea-pigs of the same age and weight that had previously been infected with the disease from the same source, gave three of them subcutaneous injections of O. T., and the other three intravenous injections of the same preparation, only lessening the dose one-third. I found that the three which received the intravenous injections reacted in from four to eight hours sooner than the three which received the subcutaneous injections. This was repeated several times with the same results. Changing the animals around, so that the three which received the intravenous injections at first, now received the subcutaneous, and *vice versa*, produced the same results, showing that I had absolute control of the reactions and proving that the intravenous method was the best way to give the remedy to get quick results. This has been further borne out by clinical results on patients.

[3] Hamburger: Wien. klin. Wchnschr., July 16, 1908.

[4] Maragliano: Die specifische Therapie der Tuberkulose, Tr. Internat. Cong., 1908.

The true fundamental principle, underlying all therapeutic measures in the effort to secure the arrest of the tuberculous infection, is that of conservation of strength and augmenting the inherent resisting power of the patient. The physician should study each case separately and all the time, because the susceptibility to tuberculin varies in different patients, as well as in the same patient at different times. As Hammer[5] says: "As a first condition for its harmless use, it is certainly necessary that the physician who desires to add it to his therapeutic equipment must be experienced enough to be able to judge even the slightest sign of reaction."

The most important rule to remember is that too little never injures, while too much may result in a strong reaction, which is to be avoided. Those who have made use of the subcutaneous method of administration know that at times, in spite of all precautions used, an abscess will occur, especially when the B. E. preparations are used; and everyone knows what effect this has on the mind of the patient as to the advisability of continuing the treatment. These bad effects can be avoided by using the intravenous method and, as stated before, results will be quicker.

Koch pointed out that success would be secured in the application of the treatment in the earliest stages of the disease. We go further to-day and say that the remedy should be administered before any of the ordinary symptoms of the disease manifest themselves. After three years' use of tuberculin, I can say without hesitation that treatment can be carried out in all cases, even in the most advanced, when there is reacting power, without danger. I have never seen any harm result, in spite of the fact that I have not picked my cases for treatment, but have taken them in all stages of the disease. On the contrary, I have found under the use of tuberculin a hard, irritating cough easing up, a tenacious sputum becoming thinner and easier to raise, and the appetite increasing, in cases that were hopeless for any marked improvement, and under such results it cannot be denied that the resisting power of the whole organism had been raised.

In giving tuberculin or any other preparation intravenously, great care is necessary that absolute asepsis is secured, that the solutions used are freshly made and are sterile, and that the needle and syringe are thoroughly sterilized. I prefer and use a Sub-Q Tuberculin syringe with a 27¾ gauged needle. The syringe is graduated to 100 parts and contains 1 c.c.

As to the technic of the injection, selecting as a site the veins in the hollow of the elbow, I have the patient hold the arm parallel to the body, and open and close the hand rapidly for a minute. This with the application of a rubber strap applied above the elbow by an assistant, makes the veins prominent and easy of access. Now I have the patient close the hand tightly, then I tighten the strap, wash the site thoroughly with alcohol, inject the solution slowly, and withdraw quickly, elevating the arm for a moment, loosening strap and opening hand, seal the puncture with collodion. No other dressing is required.

I use the O. T. and B. E. preparations and make my own solutions. I usually commence treatment, in a suitable case, with a dose of 1/10,000 to 1/1,000 mg. of tuberculin, drawing first into the syringe about 05 lines of the diluent, then the required amount of tuberculin, and again the diluent to about 15 or 20 lines, seeing that all air is expelled from the syringe. For a diluent I use a 15 per cent. solution of atoxyl. Care must be taken in the preparation of the atoxyl solutions, as the drug is very unstable and spoils rapidly. A yellowish color shows that chemical decomposition has taken place and the solution should be discarded; otherwise if used, there will be symptoms of arsenical poisoning. For the past year I have had it prepared for me with the addition of 4 minims of chloroform to the ounce of solution, which has the effect of preserving the solution for some time, and as I use only about 15 lines of the solution, or about ⅓ gr. of the salt, the amount of chloroform has no effect on the patient that I can see. Large amounts of phenol (carbolic acid) and its preparations are used as a preservative in antitoxin, and yet we never hear anything of its effects when used in this manner. Using small amounts of atoxyl, as I do, I have never had any of the bad results reported by others, such as atrophy of the optic nerve. I think that these deleterious effects are caused by using either too strong a solution or an impure salt. I have given thousands of injections without any bad effects. I have found that atoxyl is a powerful adjunct to tuberculin in producing phagocytosis, which is one of our aids in producing immunity. Dr. Ward of Philadelphia is advocating the intravenous use of nuclein for the same purpose in tuberculosis, and from his reports and others it looks as if we had another valuable aid at our command in the treatment of this disease. I have always relied on nuclein by the mouth in tuberculosis but have never used it intravenously. Atoxyl has been used with marked benefit in cases of pernicious anemia, and is especially lauded by Mendel of Essen.

The increase in dosage of tuberculin must be governed entirely by the signs of reaction, both local and systemic, and one reaction must have subsided before another treatment is given. Some of the symptoms of reaction are a slight rise of temperature, increased rate of the pulse and respiration, headache, aching of the limbs, increased cough and expectoration, loss of appetite, and so on. These symptoms will vary in intensity according to the case and the amount of tuberculin used. These, though they may be slight and seem insignificant, must be noted, and caution used before increasing the dose or even repeating it. As to the interval between injections, there should be a lapse of from three to seven days, depending on the case and susceptibility. The physician should individualize each patient so that he will be able to recognize any deviation from a normal condition, caused by the injection, because the recognition of the slightest sign of reaction will be his best protection against danger.

In order to secure the immunizing effect of tuberculin and its preparations it is not necessary, as we once thought, to give large enough doses to produce marked reactions, but just enough to keep below this reacting point. This will vary in each case and under different conditions in the same case, and must be watched carefully; hence the importance of individualizing. I believe in starting the patient on small doses and gradually increasing the dose until I reach the patient's tolerance. This will require from six months to two years or even longer in some cases. I have seen all symptoms disappear within three months in very early cases.

Toxin tolerance as a method of treatment has been strongly supported by Sahli, Denys and Trudeau. The former two look on toxin tolerance as the only object, while Trudeau believes that mild reactions are of benefit. If it is at all possible, I think it is best to avoid all marked reactions, and this can be learned by experience.

---

[5] Hammer: Value and Practicability of the Use of Tuberculin, Tr. Internat. Cong., 1908.

Specific action consists in the production of a congestion more or less marked out, at the site of the infection —a congestion which can be demonstrated by examination, whenever the disease is superficial in the lung, or when the larynx is affected. Recognizing this congestion enables us sometimes to diagnose latent tuberculous foci when other symptoms are absent.

It is my plan in treating patients to put them to bed for at least a week prior to taking treatment, have the temperature taken every two hours and urine and sputum examined, so that the exact condition can be determined and the subsequent injection watched with greater accuracy. If there is no rise of temperature I advise the patient to rest for a few days to secure complete relaxation, and see to a thorough flushing of the system. These precautions enable us to estimate the size of the dose which is one of the most important parts of the treatment.

I regard the opsonic index as a test of accuracy, but impractical, because when a number are taking treatment it takes up too much valuable time. The technic is too delicate and the results so often so difficult to interpret, that there is little hope of its ever proving useful in establishing an early diagnosis, or in guiding us in the treatment, when we have the clinical signs to guide us without the aid of trained observers and special apparatus, which the taking of the index requires. I think that studies and investigations made by such observers and with such apparatus are important and essential for the improvement of the practical side of the subject, as demonstrating the active and comparative value of different preparations, as well as showing us that the products of the tubercle bacillus act in a truly specific manner, by inducing active antibacterial or antitoxic immunity. In active antibacterial immunization specific amboceptors for tubercle bacilli can readily be demonstrated in the blood-serum of treated patients by the hemolytic method of Gengou.

From my own experience, and watching the results of others, I consider that we have at our command in tuberculin and its preparations, when used intravenously, powerful remedies for good when used rightly, but capable of doing much harm when used wrongfully. Until we have a better method we must consider it of the greatest importance in the treatment of the disease, to bring about a more general use of the intravenous method of administration; I feel confident that once the physician has used it in this way and has found that he can secure the best of results with small doses, less reaction, less discomfort to his patient and likewise to himself, and absence of all pain and swelling, he will never use it any other way, and will simply wonder why he had not used it so before. To secure this end it will be necessary that every physician should acquaint himself with the method of employment, the dosage and the behavior of the remedy, and it goes without saying that he should have a more thorough knowledge of the disease in the early stages than the general practitioner has to-day.

I want to report the results secured in ninety-five patients treated by me in the last three years. Of these, forty-eight were incipient cases, thirty-two moderately advanced, and fifteen far advanced. Of all these patients, 80 per cent. had cough, 78 per cent. expectoration, 38 per cent. hemorrhage, 15 per cent. pleurisy, 35 per cent. dyspnea, 75 per cent. loss of appetite, 35 per cent. night sweats, 30 per cent. hoarseness, 5 per cent. involvement of the larynx, 90 per cent. fever, and 100 per cent. loss of weight. On their discharge, classified according to the National Association, in the progressive stage, or unimproved, there were thirteen, or 86.66 per cent., in the improved stage six, in the arrested stage, physical signs stationary or retrograding for at least three months, twenty-eight, or 87.5 per cent.; in the apparently cured, signs of healed lesions for one year under the ordinary conditions of life, forty-eight, or 100 per cent.

A word as to the danger of the production of thrombosis and embolism, which has been one of the strongest arguments of the subcutaneous advocates against the intravenous method, and the stumbling-block to so many who really wanted to use the intravenous injections. I will say that in my opinion this is purely imaginary, for if proper asepsis is used and the solutions are sterile there is absolutely no danger. I have never had any such trouble, though treating patients in all stages, nor have I heard of it happening to others when the proper care was taken. It is not tuberculin alone that is going to cure patients, but it is a combination of all methods, fresh air, proper nourishing food, abundance of sunshine, regulation of the habits, tuberculins and autogenous vaccines rightly used and at the right time, by experienced men, that will bring us to the time when we can safely say that we have at last conquered the disease.

But it is incumbent on us to gird our loins, take a fresh hold, educate the general practitioner, and then the layman, to the effect that tuberculosis can be cured, urge the necessity of getting them under treatment and in proper surroundings as quickly as possible, urge on our statesmen the necessity for the erection of state sanatoriums where the people of little means can have the best of care and treatment; also for the establishing of day camps for early cases, and for the open-air schools for afflicted children, which have been tried in the eastern states with such marked success.

I must condemn the action of some physicians who place a syringe and a bottle of tuberculin in the hands of their patients for them to use on themselves. I have had several of these cases fall into my hands. As Pottenger[6] says:

> Any man should be capable of using these remedies if he has sufficient intelligence and sufficient determination to acquire a knowledge of their action and the proper method of their use, and if he will familiarize himself thoroughly with tuberculosis. It is just as rational to put the surgeon's knife in the hands of a blindfolded physician, as to put these specific remedies in the hands of a man who does not understand both them and the disease to be treated by them.

As the author was referring to physicians, what must the danger be when laymen try to use it!

Some assert that meteorological conditions may be disregarded in the treatment of tuberculosis—that the climatic factor may be ignored in all cases. This is wrong. Bonney[7] says:

> The fact that individuals recover from incipient tuberculosis without climatic change is no more to be considered as an argument against the wisdom of its intelligent application in individual cases, than is the recovery without operation of a given patient with appendicitis to be considered a reflection on the general expedience of surgical interference.

As Dr. Knight says, "If weather conditions make no difference, why do patients improve at one season more than another?" as we all know is the case.

---

[6] Pottenger: Pulmonary Tuberculosis, 1908, p. 206.

[7] Bonney: Pulmonary Tuberculosis and Its Complications, 1910.

Many of the effects of climate on the human system are well known, and there is no reason to suppose that the tuberculous patient is exempt from the ordinary laws of Nature in this respect. It is not so easy to live the outdoor life at rest or in activity in a place where fog and rain, snow and cold, stormy weather prevails, as it is in one where week after week passes without a cloud in the sky or a drop of rain fall. And what state in the Union has such a glorious climate as ours; what state has the combination of desert and valley, mountain and sea, giving us almost any altitude and kind of air we desire for the different classes of cases? And what state has men better versed in the diagnosis and treatment of this disease than we have here in California—such as Rothschild of San Francisco, Pottenger of Monrovia, Bridge, Barlow, Cole and Browning of Los Angeles, and many others who are doing such a noble work among us?

A word as to the physician himself, for, after all is said and done, as Dewey said of his gunners at Manila, "It is the man behind the gun that does the work." In the treatment of no other disease does the personal equation of the attending physician have such an important bearing. It is *the man* who administers the remedies who produces results. If he is capable of impressing his will and personality on his patients he can get the closest supervision of their lives. Cheerfulness in a patient aids in his recovery, for good spirits is the best medicine, and the sunshine of a smile can dissipate many a cloud. From the doctor should come the will, the interest, the cheerfulness and enthusiasm for the patients.

ABSTRACT OF DISCUSSION

Dr. Max Rothschild, San Francisco: The varied opinions of different authorities in regard to immunization and the divergent views of other authorities in regard to the effect of the different tuberculins show clearly that we are still in a condition of deplorable uncertainty in regard to immunization and treatment with tuberculins. Hypotheses and theories have been published, accepted, and condemned. Statistics have been given by which reliable authors have tried to prove that the use of tuberculins is misjudged; that the method has no merit whatever, and that just as good results have been achieved with proper dietetic, climatic and physical treatment. On the other hand, other authorities, just as reliable, show by their statistics that such results as theirs could be achieved only by the use of tuberculins. I am a strong believer in tuberculin. Carl Spengler and his followers claim wonderful results from their immunizing bodies; another school asserts that treatment with these bodies is ridiculous. If I had the time, I could bring up many other points in which the opinions of well-recognized authorities are directly opposed. We must admit that as yet we have only a little absolute knowledge of immunization, as well as of the way in which the different tuberculins act, and of the ultimate results. We know very well that we can produce immunity against certain poisons and toxins; but we do not definitely know where these immunizing bodies, or antibodies, or antitoxins, are to be found in the system. The theories of phagocytosis, opsonins, agglutinins, precipitins, etc., have all been very alluring and attractive, but they have helped our real knowledge very little. We know that we can produce immunity against tuberculins, but this immunization against tuberculins does not produce immunization against tuberculosis. This is a most important fact, which we are apt to overlook. For the administration of tuberculins, two methods exist at present. Koch's school endeavors to work the tuberculins up to large amounts. Sahli and his followers, on the other hand, try to avoid all reaction, and use small amounts of tuberculins. The latter method gives good results, is not dangerous, is a better way for the practitioner, and for ambulatory treatment. I have used it for a number of years; in fact, I had advocated it quite a while before Sahli's first publication appeared. I hope not to seem immodest if I mention my first paper on the subject, which I read in 1906 before the San Francisco Medical Society, in which I gave my experience with intravenous injections of atoxyl and tuberculins for the first time. In this paper I called attention to four points which, in combination, had given the most satisfactory results: keep your tuberculous patients in bed as long as you can, have them stay out doors in the fresh air day and night, use tuberculin in combination with atoxyl, intravenously, and avoid reactions. This brings me to the end of Dr. Shepard's paper, where he recommends the use of intravenous injections. I have used only this method for the last eight or ten years. I like it because it is clean, accurate and painless; and because the negative phase after the injection is shorter, and the positive phase longer, than after a subcutaneous injection. I do not maintain that it is better than other methods—it is to a great extent a matter of personal like or dislike—but I believe, with Dr. Shepard, that anyone who tries it for any length of time will become an advocate of this method.

Dr. Edward von Adelung, Oakland, Cal.: In private practice when asked to take care of a tuberculous person should we not always consider what we have learned from pathology, that the children of tuberculous parents are nearly always infected? As practicing physicians we should not consider our duty performed, especially to the children of a tuberculous family, until we have made it clear to the family that it is almost a certainty that the children are already infected. This point having been settled, the children of tuberculous persons should be put under treatment immediately. It does not seem rational to treat the tuberculous parent of a family and leave the children to fight the battle alone for years against the implanted tuberculosis. If tuberculin is of value, as I believe it is, to increase tissue resistance to tuberculosis, the time to use it is as soon as infection occurs. Not only the tuberculous parents but those associated with them should be given prophylactic treatment and tuberculin.

Dr. F. M. Pottenger, Monrovia, Cal.: In regard to the method of intravenous administration, I think that it, like the choice of a preparation of tuberculin, is largely an individual matter. I believe that any preparation of tuberculin is of value. I also believe that it can be used in any way in which it can be made to reach the circulation. I am often asked what preparation of tuberculin I would suggest in a given case. I always reply: "The one which the physician who is expecting to treat the patient knows best how to use." My reasons for preferring subcutaneous to intravenous injections are that they are simpler and less hazardous, although there should be no risk when intravenous injections are given correctly.

It is probable that tuberculin is changed by the first cells with which it comes in contact when it enters the body; and that, if antibodies are to be produced, they are largely produced by the cells at the point of inoculation. Probably one reason why tuberculosis does not heal out more often by the natural tuberculin which is given out from the foci of infection is that the cells which first receive the tuberculin stimulation are injured and unable to respond in the production of antibodies. It is possible that they may destroy the tuberculin without producing antibodies.

When tuberculin is introduced intravenously it passes directly to the lung and its force is spent in stimulating these same injured cells, while, when administered subcutaneously, its force is spent on the local cells at the point of inoculation; which should be better able to respond. I also believe that the slower absorption from the subcutaneous route is an advantage.

Dr. Gerald B. Webb, Colorado Springs, Colo.: In general the inoculation of toxins by the intravenous method yields the smallest amount of immunity. The subcutaneous inoculation of toxin yields more antitoxin. I would ask Dr. Shepard if he has measured in any way the antibodies produced by the intravenous method. Latham of London advocates the stomach route for tuberculin. As I pointed out in a paper earlier this morning, this is a hypoblastic route for treating disease of a hypoblastic structure. I do not agree with Dr. von Adelung that all children who react to tuberculin should at once be treated with tuberculin. The fact that 95 per cent. of children in certain communities will react to tuberculin at the age of 12 should be interpreted as Nature's crude way of vaccination. The hypersusceptibility produced is in a certain degree protective to further infection.

Dr. Charles A. Shepard, Needles, Cal.: I have used atoxyl for years in these cases. I have never seen any harm result, but I employ a much smaller dose than others have advocated, using only ⅓ to 1 gr.; I think it is of great benefit as an addition to tuberculin in producing phagocytosis. I think tuberculin is a most valuable agent used as a prophylactic in children whom we find to be tuberculous. In answer to Dr. Webb, we did not measure the difference in the antibodies intravenously and subcutaneously. We simply went by the signs of reaction.

A PLEA FOR LARGER INCISIONS AND MORE THOROUGH EXAMINATIONS IN ABDOMINAL SURGERY *

JAMES E. MOORE, M.D.
MINNEAPOLIS

While some surgeons make ample incisions and a thorough examination as a matter of routine, there are many more who do not do so, and it is with a hope of being helpful to this latter class that this paper is written. The average surgeon is prone to do his abdominal work through too small an opening. He points with pride to an inch and a half scar after an appendectomy, and a two and a half inch scar after an operation for the relief of pathologic conditions in the pelvis.

We acquired this habit, first, because of our earlier experiences with ventral hernias, which were not uncommon in the practice of every operator, in which, naturally, the smaller the original opening the smaller the subsequent hernia. Then men with dextrous fingers vied with each other to see who could do his work through the smallest opening. With our improved technic stitch abscesses and infected wounds are practically eliminated, and a ventral hernia is a rare sequel; hence this reason for a small opening no longer obtains. It would be very discomfiting to us if we could fully realize how often we have left unrecognized pathologic conditions because our opening was too small to admit of a proper examination, and because we had not acquired the habit of making a thorough examination of the whole abdominal contents in every instance.

When made at one of the accepted points of election there is no valid reason why an opening should not be amply large to permit the introduction of a hand, and, if need be, an arm, for a thorough exploration of the most remote corners of the abdominal cavity. It is infinitely better to make the opening large enough to admit the hand without force than to contuse the edges of the wound by a forcible introduction of the hand or with retractors. Faulty wound-healing has very often been due to too great or too prolonged pressure from retractors, or to forcing a tumor through too small an opening.

With our present technic a large opening will heal just as surely and as perfectly as a small one, and there can be no objections to the larger opening except those based on our former and less perfect technic. Our natural prejudice against a long cicatrix for esthetic reasons, is no longer tenable because the objection is only a fancy, while the fact is that we can do our patients much better service through a longer incision. The laity are now so accustomed to abdominal scars that the size of the scar is no longer a matter of importance to them.

At one time I was quite proud of the fact that I could remove an appendix through a McBurney incision just large enough to admit my index-finger. My pride sustained several serious jolts, however, when I was called on to perform a later operation for the relief of conditions overlooked at the first one. Doubtless many other patients who were not relieved by my esthetic operation went to other surgeons for relief, the result being that I was discredited and my patients were subjected to the suffering, danger and expense of a second operation, and had two scars instead of one, all for the sake of a dainty little scar in the first instance. Every surgeon present must admit that he has had like experiences unless he was wiser than I and made large incisions from the first.

These experiences led me to question the merit of the small opening, but I did not fully realize the error of my ways until I had the following experience. A young man was brought to me for immediate operation with a diagnosis of acute appendicitis. He gave the history of having had a number of previous attacks, but none so severe as the present one. He had been ill but a few hours, had vomited repeatedly, and was suffering very severe pain all through the abdomen, but worse in the right iliac region. His whole abdomen was very rigid. There was marked tenderness over McBurney's point. A McBurney incision was made through which a slightly swollen and congested appendix was removed. Some serum escaped through the wound. The condition of the appendix did not seem serious enough to account for the severity of the symptoms, so a finger was passed into the opening and by forcibly depressing the abdominal walls with the knuckles a distended viscus could be felt. The original incision was closed, and a liberal median incision made through which a hand was introduced, and an intussusception of the ileum into the cecum found. The intussusception, which was caused by an inverted Meckel's diverticulum, was reduced, the diverticulum removed and the patient restored to health. The real condition here might, and ordinarily would, have been undiscovered through the short incision, and the patient would have lost his life unless subjected to a second operation very promptly. As it was, two incisions were made, whereas one of the right size and properly located would have sufficed.

The making of large incisions will not prevent oversights unless a thorough examination is made. A very common mistake made by operators is to be content when they have relieved one condition without looking for others. Even when a condition is found seemingly sufficient to account for all the symptoms, a careful search should be made for others. When one adhesive band is found there are very likely others. An appendix may be removed leaving gall-stones behind, or *vice versa.* Gall-stones may be removed from the gall-bladder and one or more left in the common duct. One typhoid perforation may be closed and others left. Since following the practice advocated in this paper my findings have been so numerous and my surprises so great that I wonder I ever had the temerity to operate through a small incision. The examination should be systematic and thorough, and the operator should never be content until he has found conditions that will fully account for all the symptoms. The appendiceal region, the pelvis, gall-bladder and stomach regions should always be examined as a matter of routine. Most surgical conditions will be found in these regions, but the following experience impressed on me the fact that grave conditions may be found in most obscure and unsuspected regions:

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

A country physician recently telephoned to me that he was sending a patient on the next morning's train for an operation for appendicitis. He said, "My diagnosis is appendicitis, but the symptoms don't check up right. Do whatever is necessary for the boy." The patient, a boy of 16, had a normal temperature, an accelerated pulse, a slightly distended abdomen, with tenderness most marked in the lower right quadrant. The most marked feature in the history was that he had been suffering for some weeks with severe cramps and occasional vomiting immediately after eating. An incision was made along the margin of the right rectus, and the appendix was found slightly congested and swollen, but in no condition to account for the symptoms. On inspection the intestines looked normal, but there was some serum present. The danger regions were all carefully examined and nothing found. Beginning at the ileocecal valve a search was made for a Lane's kink, and a small Meckel's diverticulum was found from which a long narrow band extended to a point high up and deep within the abdomen. Underneath this band was a large loop of bowel, not tightly constricted, but the lumen of the bowel was reduced about one-half. The intestine was thickened and sore at the point of constriction, showing that it had been in that position for some time. It was evident that the patient's pain after eating was due to the peristalsis set up by the food. The removal of the diverticulum and band were followed by recovery, with complete relief from pain.

The appendix is so frequently the seat of trouble that the tendency is to make a diagnosis of appendicitis on insufficient grounds. The diagnosis of appendicitis is about the easiest of all diagnoses of intra-abdominal conditions, yet the diagnosis of appendicitis is probably the most frequent wrong diagnosis made. This may be accounted for partly by the fact that appendicitis so frequently complicates other conditions; but it is doubtless due often to the natural tendency of mankind to jump at conclusions. The mistake of removing the appendix when the real cause of the patient's suffering is elsewhere can be so easily avoided by a thorough examination through an ample opening that it seems almost superfluous to argue the matter. Since adopting this method as a routine practice I have found unsuspected gall-stones, appendicitis, adhesive bands, Meckel's diverticulum, internal hernia, Lane's kink, intestinal adhesions, tuberculosis and other conditions too numerous to mention, most if not all of which could not possibly have been certainly diagnosticated by any other method.

The location of the incision is not so important as its size. When the location of the pathologic condition is not definitely known, or when it is definitely known to be in the pelvis or lower abdomen, the median incision is undoubtedly the best, as it affords easy access to all parts, and does the minimum amount of harm. In the upper abdomen the incision should be through or at the inner edge of the rectus because of the presence of the triangular ligament in the median line.

Useful and anatomically correct as the McBurney incision is, it is undoubtedly the one which is responsible for the greatest number of oversights, because it is satisfactory only when it is made small. It can be made large, but in so doing much greater damage is done to the muscles and nerves than by a median incision, and its location is not nearly so satisfactory for general work. It is very much easier to remove an appendix through a median incision than it is to do pelvic work through a McBurney incision. The muscle-splitting incision should be restricted to cases of suppurative appendicitis in which there is no indication for going far into the abdomen, and to unmistakable cases of chronic appendicitis without complications.

In other words, the day of the short incision is past in all but exceptional cases.

STUDIES IN INFARCTION

EXPERIMENTAL BLAND INFARCTION OF THE KIDNEY AND SPLEEN *

HOWARD T. KARSNER, M.D.
Assistant Professor of Pathology, Harvard Medical School
BOSTON
AND
J. HAROLD AUSTIN, M.D.
Associate in Research Medicine, University of Pennsylvania
PHILADELPHIA

The early history of the study of thrombosis and embolism is so completely reviewed in the articles of Virchow,[1] Cohn[2] and Welch,[3] that it seems hardly necessary at this time to consume time and space with its detailed presentation. It is very evident that Galen, Vesalius, Lancisi, Bartoletti, Bonetus, Boerhave, and Morgagni had, in a general way, fairly clear ideas as to the nature of these conditions, although, as would naturally be expected, they made no sharp distinctions between the two. Laennec's description of hemorrhagic infarction of the lung, under the name of pulmonary apoplexy, was most illuminating, although he seems to have had little knowledge of the nature of infarction in general. Rokitansky[4] had a much broader conception, but failed to differentiate the possible causes. The results of Cohn's experimental work, as well as of Pannum's,[5] are not conclusive, in that infection and secondary inflammatory changes were almost constant complications.

In 1872 Cohnheim[6] published his "Untersuchungen." The largest part of his work was done on the frog's tongue, but he also extended his experiments to the rabbit's ear, guinea-pig's mesentery and the mammalian kidney. He formulated the conception of end-arteries; a distinction which later observers, notably von Recklinghausen,[7] have shown to be less absolute than Cohnheim taught. Disregarding the earlier work of Cohn and of Blessig,[8] Cohnheim concluded from his own work

that the blood in a hemorrhagic infarct represents a reflux from the veins.

Von Zielonko,[9] working under von Recklinghausen, studied areas of obstructed circulation in the web of the frog's foot. He showed conclusively that, at least in the web of the frog's foot, the blood enters and distends the capillaries of the infarcted areas from the capillaries of the neighboring areas and never by a return flow from the veins. He also showed that the arterial pressure in the surrounding areas is an important factor in determining the degree and rate of hemorrhagic extravasation. He noted at the end of five or six days the beginning decolorization of the hemorrhagic area. Kossuchin,[10] in 1876, working on the frog's tongue, reached practically the same conclusions; and in 1878 Küttner[11] demonstrated, by injections, the free capillary anastomosis existing between the bronchial and pulmonary circulations in both amphibian and mammalian lungs, and thus opened the way for an explanation of the hemorrhagic character of pulmonary infarcts. A more effective influence, however, in overthrowing Cohnheim's teaching was Litten's[12] repetition, in 1881, of Cohn's and of Blessig's experiments on the kidney. After ligating the renal artery of the rabbit, he obtained greater hyperemia and hemorrhage when he ligated in addition the renal vein, than when he left it open; on the other hand, if he also ligated all sources of collateral circulation, the hyperemia and hemorrhage were reduced to a minimum even although he left the renal vein free. Von Recklinghausen[13] attributed to partial hyaline thrombi, which he observed in the capillaries of hemorrhagic infarcts of the lungs and spleen, an influence which raises the pressure in these capillaries and predisposes to diapedesis. Brown-Séquard[14] had pointed out the possibility that lesions of the vasomotor nerves accompanying the obstructed artery might be a factor in the capillary dilatation. Recently Bier[15] has emphasized the same possibility and has shown that, after section of the artery and vein of the hyperemic area, the blood still remains in the dilated capillaries; whence he concludes that the capillary dilatation is to some extent independent of the transmitted arterial or venous pressure. Mall[16] found it exceedingly difficult to inject from the mesenteric veins into the capillaries and impossible to inject from the veins back through the capillaries into the arteries.

Detailed studies of the anatomic and histologic changes in infarcts of the spleen and kidney, at different periods after infarction, have been made by several observers. Beckmann[17] believed that the infarcts of the kidney were seen as pale infarcts with little evidence of blood, and opposed Rokitansky's view that the pale renal infarct represented a decolorization of the earlier hemorrhagic infarct. Later Weigert[18] emphasized the same conception of anemic infarcts as distinct from hemorrhagic infarcts, and in spite of much evidence to the contrary, his view attained wide general acceptance. Both von Recklinghausen and Thoma[19] apparently accepted his view. In 1877 Argutinsky[20] studied renal infarcts in the dog twenty-four hours and seven days after the injection of wax pellets into the aorta through the crural artery. Contemporaneously Uhthoff[21] made a similar study, using mercury instead of wax. Both observers noted the presence of hemorrhage, or of pigmentation the result of hemorrhage, widespread throughout the infarcted area, thus opposing the theory of Beckmann and Weigert. Talma[22] studied rabbits in which he ligated one branch of the renal artery. In the first twenty-four hours he found the infarcted area swollen and red, but laid stress on the hyperemia rather than on the hemorrhage. Foa[23] in a similar series found that a few seconds after ligation, the infarcted area might be pale, but that at the end of twenty-four hours it was swollen and red. He noted the presence of moderate hemorrhage.

In spite of this work, Thoma[19] in 1894, still described the renal infarct as pale from the outset. More recently Beattie and Dickson[24] report work done by Forbes[25] under Greenfield's direction, in which seeds were injected into the arterial circulation. In the kidney they note, in the early stages, congestion with slight hemorrhage, most marked in the medulla; later, pallor develops both centrally and peripherally, associated with necrosis throughout the infarct. In the spleen they find hemorrhage to be very conspicuous in the early stages, with decolorization appearing later.

Regarding regeneration in the kidney, Litten, Petrone,[26] Arnold,[27] Weigert, Podwyssozki,[28] Thorel[29] and Pearce[30] all have noted epithelial proliferation after various renal lesions, but no true tubule reproduction and no formation of new glomeruli. Pisenti[31] alone claims to have seen, after excising small pieces of kidney, some attempt at the formation of glomeruli and true tubules. Except in those cases associated with abscess formation, organization of the infarcted area has been noted by all observers, beginning, during the course of the first week after infarction, at the periphery and gradually extending toward the center. Very recently MacNider[32] has presented a series of experiments on the cat, in which he ligated one branch of the renal artery and made histologic studies at intervals of from twenty-two hours to ninety days, especial attention being given to the regenerative changes.

The present group of experiments represents the first of a series in which is contemplated the study of infarc-

tion in all its phases. Up to this time the greater number of investigators in the field have studied not only infarction, but also the closely related subjects of thrombosis and embolism. That these two latter conditions, of importance in the etiology of infarction, have distracted attention from the infarct itself is reflected in the insufficient reports on the gross and minute anatomy of infarcts and in the incompleteness of experimental procedures to elucidate the various changes found. We propose to study the anatomy of the infarcted areas in various stages, both under normal conditions of circulation and with certain experimental variations in the general circulation of the organ in question; we shall take up certain problems in physiology and physiologic chemistry suggested by our observations and shall extend the investigations to all the available organs of the body so as to be able, on the completion of the study, to make definite and conclusive deductions.

METHODS

The study presented at this time concerns infarction in the kidney and spleen of the dog under normal and variously altered conditions of circulation. In the spleen the vascular arrangement is comparatively simple and the only practicable experimental variation in circulation of any significance was the cutting off of the general arterial supply. In the kidney, however, the fact that the organ is supplied and drained by renal, ureteral and capsular vessels makes matters more complicated. With the capsular vessels we include the anastomoses with the adrenal and lumbar circulation. It was, therefore, necessary to study the kidney under the following conditions:

1. With normal circulation.
2. With renal artery ligated.
3. With renal vein ligated.
4. With renal artery and vein ligated.
5. With renal artery, vein and ureteral vessels ligated.

In female dogs the additional anastomosis with the ovarian circulation is usually very rich and required special ligation. In all cases with ligation of the ureteral vessels any possible flow of urine from the kidney was provided for by the insertion of a small aluminum cannula into the ureter, the silk being tied around it. Decapsulation in addition to universal ligation was not practiced, since it was found that it led to extensive suppuration of the kidney and, moreover, the universal necrosis under these conditions rendered the study of the infarcts impossible.

In ligating the splenic artery, particular care was taken to tie off also the branches anastomosing with the gastric artery. On several occasions simple ligation of the splenic veins was tried, but the early infarcts were entirely obliterated by the swelling resulting from this procedure, and the later ones showed no marked differences from those of normal spleens, with the exception that the entire mass of the spleen was much diminished and the organ pallid in appearance. Accordingly, it was felt that no additional information of value could be obtained from an extended series of this kind. The dogs in all the groups were killed two, four, twelve, twenty-four, forty-eight hours, and four and seven days after the production of the infarcts.

The operations were all done aseptically and under deep ether anesthesia. A median abdominal wound was made from 2 cm. above the umbilicus to the pubis and the left common iliac artery exposed. For the insertion of the emboli an annealed soft copper tube, 35 cm. long and 1 mm. in caliber, provided with a flexible steel obturator, was used. After orientation experiments with begonia, aldike clover, mustard and tobacco seeds, the last were found to be most satisfactory, and were used uniformly throughout the series. About 50 seeds were placed in the end of the copper tube in a space left by drawing the obturator back for a distance of 2 cm. The instrument was inserted into the iliac artery and as far up the aorta as desired. It was not long before sufficient skill was acquired to avoid abrasion of the intima of the aorta. For the production of splenic infarcts it was necessary to have the end of the tube 2 to 3 cm. above the origin of the celiac axis and to occlude, by pressure with the finger, the superior mesenteric, renal and right common iliac arteries. For the production of renal infarcts the end of the cannula was placed just below the origin of the celiac axis and the superior mesenteric and right common iliac arteries occluded. In those cases in which both renal arteries were left open, it was found that placing the cannula at any point above the origin of the right renal artery resulted in more frequent infarction of the right kidney than of its fellow; and when both organs were infarcted, the infarctions were more numerous in the right. For this reason most of the work was done on the right kidney. It was necessary to occlude the mesenteric artery temporarily, so as to avoid the entrance of seeds into the arteries of the intestines and the consequent production of gangrene. Where several renal vessels were ligated, the artery was tied first, then the vein, then the ureteral vessels, and, in females, the ovarian circulation.

Heavy white silk (Corticelli EE) was used for all ligations. The wound was closed by the usual surgical procedure, and after the given time had elapsed, the animals were killed with chloroform. At autopsy the success of the ligations was carefully determined, gross notes and diagrams were made, the tissues fixed in Zenker's fluid, embedded in paraffin and stained with Delafield's hematoxylin and alcoholic yellow eosin. The minute study of the slides was aided by and correlated with the gross diagrams and notes.

RESULTS

Grossly, the experimental infarcts of the kidney became distinctly visible at the surface of the organ in from three to five minutes after the injection of the seeds into the aorta. The first noticeable change was the appearance of a brilliant purple color which occupied a large part of the infarcted area. This congestion gradually extended until, in about ten minutes, the infarct in its entirety was sharply defined. (In only one infarct was there any exception to this rule. This was in a somewhat fibrosed organ, the infarct appearing first as a pallid area with a purple marginal zone, the entire area becoming purple, however, in less than two minutes after the infarct became distinguishable.) No definite swelling was noticeable in this early stage, probably because of the tension of the kidney capsule. At the expiration of two hours, however, the entire kidney, which at first had been of a bright pink color, became of a color so closely matching that of the infarct that the outline of the latter, in a large number of cases, was almost entirely lost. At the end of four hours, although still lacking in definition on the outer surface, the infarct could be fairly well defined in the cut surface. At this time in all the kidneys examined, the infarct was seen as a purple mass of deeper color than the surrounding kidney, rather poorly defined, moist and bloody, usually bulging on section and occasionally protruding somewhat above the surface of the organ. At this stage there was present in the vast majority of instances, a peripheral zone rarely more than 1 mm. in width, in which the tissue was somewhat lighter in color than in either the infarct or the surrounding kidney substance. The fact that this zone could not be distinguished microscopically, leads to the conclusion that it represents a zone of relative compression anemia. This pallid area remained visible for several hours, disappearing in from twenty-four to forty-eight hours, when the infarct reached the limit of its elevation and deep color and began to fade and retract. Necrosis began in the infarcts of the normal kidneys in forty-eight hours, the same being true of the infarcts in those kidneys in which the arterial supply was cut off without other interference with the circulation. After simple ligation of the vein, necrosis appeared in the infarct at the end of twenty-four hours; and with additional ligation of artery and ureter, it appeared in from twelve to twenty-four hours. Usually coincident with the necrosis, a clearly visible, but always very narrow, zone of reactive hyperemia appeared at the margin of the infarct, but congestion of this kind was by no means a constant feature. The necrosis appeared first as irregularly distributed, minute areas near the middle of the infarct, in the later stages becoming larger and fusing to form solid, fairly large masses of necrotic material. In the late infarcts (four to seven days old) where the outer surface and cut surface showed retraction of the infarcted mass, the central necrotic mass was often surrounded by a red zone, which histologically was found to be in part the remnant of suffused blood that had not undergone complete necrosis and in part blood which had infiltrated from the reactive hyperemia. Outside this zone was frequently seen a pallid zone which histologically corresponded to the zone of forming connective tissue. There is little doubt that with the progress of the necrosis, the intermediate zone of redness gradually disappears. Furthermore, in small infarcts this red zone was completely absent at the end of seven days. It must be said, however, that the sequence of gradual changes was not shown nearly so well in gross as in microscopic specimens. Indeed, it seems highly probable that the infrequence of the finding of red infarcts in the human kidney, is due to the fact that in this early stage the infarcted area is so ill defined as to be practically indistinguishable. A point of considerable interest is the fact that the infarcts were often very irregular in outline and varied markedly in general conformation, being most frequently conical, but very frequently hemispheric or cylindric.

The infarcts of the spleen became easily visible even more rapidly than did those of the kidney. They appeared as deep purple, fairly well-defined areas, usually triangular in shape near the poles or margins, but when occurring midway between the poles, extending as linear masses transversely across the organ. No portion of the spleen was more commonly infarcted than another. The most striking feature of the infarcts in this early stage is their marked swelling, which in many cases caused infarcts 1 cm. broad to project 3 to 4 mm. above the surface of the organ. At two and at four hours after infarction, the appearance of elevation was lessened and the outline of the infarct was not so well defined, probably because of the general enlargement and increased depth of color of the organ resulting from general congestion. A small percentage of the earlier infarcts showed a narrow pallid marginal zone, similar to that sometimes seen in the kidney infarcts, but again histologic examination failed to prove its nature. Necrosis did not appear in the infarcts of the spleens with unaltered general circulation until a week had elapsed, but in the series in which the splenic artery was ligated, necrosis was noted at the end of forty-eight hours. The necrosis, at first, was irregularly distributed, but later extended throughout the center of the infarct, except in one infarct in which the white necrotic mass had a central dry, red area. No zone of reactionary hyperemia was demonstrable at any stage of the condition, and it may safely be said that the only significant difference brought about in the course of the infarcts by artificially altering the circulation was that ligation of the artery caused necrosis to appear earlier than when the general circulation was not disturbed.

Histologically the infarcts presented pictures that showed very clearly the progress of the condition. In those infarcts which grossly were distinguished only with the greatest difficulty, the microscope showed unmistakable signs of focal interference with circulation and no mistake in the diagnosis was possible. Rather vaguely outlined in the early stages, definition became clearer and sharper as the condition progressed.

In the normal kidney, two hours after infarction, there was a small zone of subcapsular hemorrhage overlying the infarct, and well-marked congestion of the intertubular capillaries and of the capillaries of the tufts. The blood in both regions was distinctly conglutinated, although in a specimen taken one hour after infarction (not included in the general series and only differing in this one respect) the conglutination had appeared in the intertubular capillaries, but not in the glomerular loops. The blood at this time was confined to the vessels, with the exception of a few corpuscles found here and there in the midst of the space occupied by a very well-marked interstitial edema, and in the subcapsular space which also showed a finely granular albuminous deposit, evidently of an edematous fluid. The tubular epithelium, especially of the convoluted tubules, showed marked cloudy swelling but practically no desquamation, and the nuclei of these cells showed slight fading of the central chromatin, the margins being still sharply defined. The lumina of the tubules were somewhat enlarged because of thinning of the cells surrounding them, but were well filled with a finely granular albuminous material, probably edematous in character. The larger vessels and the vessels of the medulla showed fairly well-marked congestion, but the medulla in this, as well as in all other sections, showed no other notable changes except for moderate fibrosis in the very late stages.

At four hours the conglutination had progressed, and some of the blood in the middle of the infarct showed fading of the hemoglobin. The tubular epithelium was more markedly degenerated and showed moderate desquamation. Desquamation and well-marked cloudy swelling were also observed in the epithelium lining the capsule of Bowman. The edema had become more marked in all situations, being accompanied in the glomerulus by distention of the capsule. Well-marked pyknosis and karyolysis were present.

At twelve hours, aside from the fact that the infarct was sharply defined, there were no notable changes except in degree.

At twenty-four hours the infarct was very clearly defined and it had become possible to distinguish two zones: an outer zone in which the necrosis had evidently come on rapidly, giving the infarct its sharp definition; and an inner zone where hemorrhage had become well marked. The tubules and subcapsular spaces of this marginal zone appeared as coarsely granular, or almost hyaline, acidophilic masses and the interstices between the tubules, in the inner part of this zone, were occupied by conglutinated red blood-cells, and, in the outer part, by fresh, well-stained, non-conglutinated red cells, the latter being largely intravascular and very evidently dependent on a slight hyperemia in the surrounding living tissue. A few polymorphonuclear leukocytes were found in this zone.

At forty-eight hours the conditions were much the same, except that the center of the infarct showed hemorrhage more clearly, and the fading of the red cells had progressed to a considerable degree.

At four days the necrotic central zone was greatly increased in size. A zone of solid necrosis, seen as a peripheral zone in the preceding sections, now became an intermediate zone, due to the appearance of an outer marginal zone of growing connective tissue, somewhat poorly vascularized. No mitotic figures were demonstrable.

At seven days the fibrosis was more extensive, and occasional mitotic figures were seen in the tubules near the margin, but with no evidence of new formation of tubules.

Ligation of the renal vein resulted in several changes in the microscopic appearances of the infarcted and non-infarcted areas. The most notable change was in the blood content, which in the infarct was very much greater than in the non-infarcted area; and two hours after infarction there was seen slight, but easily demonstrable, hemorrhage into the subcapsular space and the interstitial tissue of the pulp. Edema was about the same in this as in the preceding series. The infarct became sharply defined in four hours (earlier than in the first series), showed somewhat more rapidly progressing hemorrhage and conglutination and an early fading of the masses of blood in the middle of the infarct which became almost complete at twenty-four hours. As a whole, the series was characterized by more marked circulatory alterations and more rapid degenerative changes in the parenchyma than were evident in the kidneys with normal general circulation. At four and seven days after infarction, the central zone showed a rich, very fine network of fibrin in the positions from which the erythrocytes had disappeared. The new growth of connective tissue was not especially different in progress or character from that seen in the previous series. In the surrounding kidney substance, cloudy swelling, edema, and congestion were observed very early; definite necrosis was not demonstrated; hyaline casts became evident in four hours, and rapidly increased; and regenerative changes in the epithelium were not demonstrable.

With ligation of the renal artery alone, the blood conditions in the infarct were much the same as in the series with normal general circulation, except that the blood-content of the necrosing area was less, although not markedly so. The changes in the suffused blood progressed with the same rapidity as in the first series; the infarct became sharply defined at four hours (earlier than in the first series, at the same time as in the second series); decolorization of the corpuscles was well-marked at twelve hours and progressed somewhat more rapidly than in the first, and less rapidly than in the second, series; degenerative changes in the parenchyma followed much the same course as in the second series, and fibrin appeared in the center of the infarct just as in the second series. Organization was well-marked at four days. A few mitotic figures were found in the epithelium immediately surrounding the infarct at seven days. The non-infarcted areas showed, in the early stages, well-marked capillary congestion which became much less marked after twelve hours; also moderate edema, well-marked cloudy swelling, going on to distinct necrosis in the later stages, and in the seven-day kidney the presence of hyaline casts.

On ligation of the renal vein in addition to ligation of the renal artery, the infarcts progressed in practically the same way as with ligation simply of the renal artery. This statement applies to blood-content, blood-changes, degenerative changes, and regenerative appearances. Neither did the appearance of the non-infarcted areas differ in any essential feature.

Ligation of renal artery, renal vein and ureteral vessels (and, in female dogs. the ovarian anastomoses) resulted in no distinct variation in the amount of blood in the infarct, or in the subsequent alterations in the blood, from that seen in the third and fourth series, and organization was not noticeably retarded, but the infarct became sharply defined histologically at the end of two hours (more rapidly than in any of the other groups), necrosis progressed with great rapidity (also clearly noted grossly at twelve to twenty-four hours) and no mitotic figures were found in the surrounding epithelium. The non-infarcted kidney substance was anemic from the first and showed rapidly progressing degeneration and necrosis of the epithelium. Hyaline casts were present in considerable numbers at, and after, twenty-four hours; only in the series in which the renal vein alone was ligated, had they been seen so early and in such great numbers.

Throughout all the groups careful microscopic examination showed no very marked leukocytic infiltration. The slight degree of infiltration noted was always marginal, never showed deep penetration and usually appeared at from twenty-four to forty-eight hours.

The spleen at the end of two hours showed rather poor definition of the infarct histologically, with a narrow zone of uninfarcted tissue immediately under the capsule. In the periphery of the infarct was found a marked distention of isolated blood-sinuses with but little or no extravasation. The pulp in this area showed no change, but in many instances the follicles, even though not apparently within the zone of infarction, showed slight pyknosis and karyorrhexis in those cells situated near the middle of the follicles, but not in direct apposition to the central artery. In the middle of the infarct there was more marked distention of the sinuses, more uniformly distributed congestion and very distinct extravasation. Here, also, the follicles were uninvolved by the hemorrhage, but showed somewhat more marked pyknosis and karyorrhexis than did the follicles at the margin of the infarct. Those parts of the pulp that were almost obliterated by congestion and hemorrhage showed moderate pyknosis and karyorrhexis in the remaining cells. Conglutination was moderate in the areas both of congestion and of hemorrhage. The non-infarcted areas showed no pathologic alterations.

At four hours the only changes worthy of note were somewhat more marked conglutination; more extensive nuclear degeneration and a degeneration of the protoplasm of the cells in the infarcted zone as shown by a lessened affinity for the eosin. Trabeculæ, blood-vessel walls and follicular outlines were well preserved.

At twelve hours the infarct became sharply defined by the extension of the hemorrhage into the marginal zone, which previously had shown only congestion. Conglutination was well-marked and necrosis advanced. In the pulp immediately surrounding the infarct, there was a moderately well-marked infiltration of leukocytes which, however, penetrated but a very short distance into the hemorrhagic area.

At twenty-four hours no additional changes could be demonstrated.

At forty-eight hours conglutination had reached such an extreme degree that the infarct appeared as an almost hyaline, red mass, containing the trabeculæ and small circular areas of nuclear fragments representing the follicles. At this stage the nuclei of the trabeculæ showed a marked diminution in the affinity for the hematoxylin. The marginal leukocytic infiltration was about the same as at twenty-four hours.

At four days the infarct was sharply defined and still showed a narrow zone of living tissue immediately beneath the capsule. In the margins of the infarct a few of the trabeculæ with their blood-vessels persisted apparently uninjured. From the tissue immediately surrounding the infarct, i. e., from the trabeculæ in the margin and their blood-vessels, from the fine fibrillar connective tissue framework of the living pulp, from the thin layer of living tissue underlying the capsule and from the capsule itself, a slight new growth of connective tissue, rather poorly vascularized, had developed. The infarct itself appeared as a mass of almost completely decolorized erythrocytes and many irregularly distributed nuclear fragments. In the center of this mass, the red blood-cells had almost completely disappeared and there was found a fine network of fibrin, enmeshing a relatively small number of fine albuminous granules.

At the expiration of one week, the new growth of connective tissue was somewhat more extensive; the leukocytic infiltration had almost completely disappeared, and the central area of complete necrosis and fibrin formation was somewhat more extensive. At this stage was present a very slight hyperemia in the smaller vessels outside the zone of organization, a feature not demonstrable earlier in the course of the development of the infarct. At no time could granular or crystalline pigmentation of the infarct be demonstrated.

Ligation of the splenic artery produced practically no change in the microscopic character of the infarct, except that the process extended to the capsule without any intervening rim of living cells. In the later infarcts, however, a zone of new growing connective tissue appeared between infarct and capsule, evidently taking its origin from the latter structure. Decolorization of the erythrocytes appeared somewhat sooner than in the preceding series and progressed more rapidly. Necrosis of the cells of the pulp and follicles followed the same course as in the spleens with normal general circulation. The non-infarcted tissue showed no effect of the ligation, except that, after one week, the protoplasm of the larger lymphocytes and endothelial cells showed diminution in affinity for eosin.

CONSIDERATION OF THE DATA

In the discussion of the various facts established by, and inferences to be drawn from, this study, it is proposed to take up, first the circulatory changes with especial reference to congestion, conglutination of red blood-cells, solution of hemoglobin, fibrin formation; then the progress of degenerative changes in parenchymatous and connective tissues, and finally the evidences of regeneration and organization.

A conclusion from the work that is unavoidable is that, in the kidney and spleen, all infarcts are primarily hyperemic. The term "hyperemic" is used advisedly, for in the earlier stages, at least in the kidney, hemorrhage plays a very unimportant part in comparison with hyperemia. In the spleen, the extravasation can be seen distinctly in the center of the infarct four hours after embolism, but in the kidney it does not become an important feature for from twenty-four to forty-eight hours. The hyperemia is diffuse and is much more striking in the capillaries and small vessels than in the larger arteries and veins. T[illegible] nsidered by most writers to be the [illegible] due to injury of the vessel walls. From our histologic examination this statement cannot be gainsaid; indeed there is much experimental evidence for accepting it. In the walls of the larger arteries, however, we were not able conclusively to demonstrate early degeneration; their walls were distinctive until long after the hemorrhage had appeared. This does not by any means controvert the statement in question, because diapedesis naturally would take place from the smaller vessels; vessels whose walls are not likely to be well defined under conditions such as are found in the infarcted areas. In the kidney, the early hyperemia was most notable in the intertubular and glomerular capillaries, and as it was in these places that extravasations were seen there is little room for doubt that the capillaries which are the seat of the most intense congestion, furnish the blood that later appears as extravasations. In the spleen, the sinuses of the pulp showed intense early congestion, a congestion which was not, and did not later become, evident in the follicles: the hemorrhage appeared in corresponding position and evidently came from the thin-walled vessels.

In determining the source of the congestion, arteries, veins and capillaries must be considered. It is very unlikely that the capillaries play an important part, because very early they become occluded with the conglutination thrombi, which will be discussed later. In addition, the work of Mall[16] leaves very little doubt that physiologically the capillaries soon become impermeable. The possibility that reflux from the veins plays an important part has also been ably refuted by the same writer. In addition also, the study of our specimens shows that ligation of the veins had practically no effect in varying the amount of congestion after the pressure of the arteries had been eliminated. That the general vascular pressure in the kidney has an influence on the blood-content of the infarct, was shown by the increased amount of blood in the infarct when the vein alone was ligated. Ligation of the main artery and vein was followed by the appearance of relatively little blood in the infarct, doubtless because of the relatively low pressure maintained by the collateral circulation. Cutting down the circulation to a minimum, however, as was done by additional ligation of the ureteral and ovarian circulation, was in no case followed by what might be called an anemic infarct. Where all circulation was cut off, necrosis was so extensive that no infarcted areas could be clearly seen. The assumption is obvious, therefore, that whatever hyperemia is present, is due to the dilatation of the vessels in the infarcted areas and is dependent on the arterial pressure of the surrounding, living tissue; regurgitation from the veins plays no significant part in its production.

Edema of the interstitial tissues and the presence of an excess of albuminous precipitate in the subcapsular space, were constant and early but tended soon to disappear.

Marginal hyperemia, the so-called collateral hyperemia, usually did not appear until forty-eight hours or more had elapsed. It would seem that this is a local condition dependent on the irritation of the necrotic mass, because it did not appear until necrosis was distinctly in evidence. That it is local was evidenced by the fact that variations in general circulatory conditions did not appreciably influence it.

The term conglutination, used freely in describing the microscopic appearance of the infarcts, is taken to mean clumping and fusion of the corpuscles; mere clumping, however, is of little significance because, of necessity, the corpuscles are in close apposition as they lie in the tissues and vessels. The condition appeared within two hours after infarction, gradually became more marked and reached its height in from twenty-four to forty-eight hours, and then slowly became less manifest because of fading of the corpuscles. Little change in this process was found under the various circulatory conditions, except that in the series of kidneys in which the vein alone was ligated, conglutination reached its height somewhat earlier than in the other groups. What part the heightened pressure played in this variation is problematic, but it seems likely that the chief reason why the change was so notable is that, when the vein alone was ligated, the vessels were richer in blood and the extent of conglutination correspondingly great. In the spleen, conglutination occurred much as it did in the kidney, the only difference being that it appeared to be fairly extensive in the earlier infarcts, probably because the blood is in greater masses in the distended splenic sinuses than in the smaller kidney capillaries.

Fading of the corpuscles or solution of their hemoglobin did not appear, as a rule, until forty-eight hours had elapsed. It was usually seen in the center of the infarcted mass and progressed peripherally, but even at the end of a week, at least in the larger infarcts, there was usually a fairly large mass of conglutinated, well-stained cells between the central pale areas and the marginal zone of the infarct. In none of the slides was granular pigment deposit found, and it seems probable that the hemoglobin diffused into the surrounding tissues without further decomposition. If any flow of tissue juice or plasma occurs in the vessels of the infarcted area it must be extremely slight because of the conglutination thrombi in the capillaries and the coagula in the larger blood-vessels. It is but natural to expect that the earliest and most extreme degeneration would occur centrally, because this part of the mass is furthest from the source of nutrition. It is not likely that leukocytes play any part in the removal of the hemoglobin, because none of the specimens showed deep penetration of these cells into the infarct. Indeed, with the exception of some of the later infarcts in the spleen, there was never more than a very moderate peripheral infiltration of polymorphonuclears, and in the kidney the lymphocytes were even less prominent. That venous drainage has little or nothing to do with the decolorization, is evidenced by the fact that ligation of the vein played no important part in the fading of the cells, the central pallor of the infarct appearing quite as soon in this series as in the others. The same is true of changes in the arterial conditions, for solution of the hemoglobin was quite as prominent a feature in the groups in which the artery was tied as in the group in which no vessels were ligated. It would appear, therefore, that plasmatic diffusion is responsible for the disappearance of this pigment.

Coincident with the disappearance of the hemoglobin, fibrin could be seen in the center of the infarcted area. It did not appear as heavy bands at any time, but was clearly distinguishable as a closely woven mesh of very fine threads with the typical nodes at the points of intersection. This applies equally well to kidney and spleen.

The degenerative changes in the parenchyma put in their appearance early, first as simple cloudy swelling, then desquamation, nuclear degeneration and finally at the end of about forty-eight hours, complete necrosis. All these changes reached their height in the central parts of the infarct before the marginal parts became affected, and also showed more markedly in the convoluted than in the other tubules. An interesting feature is the fact that the epithelium in the center of the infarct tended to break up into a finely granular mass, whereas that in the margin, slightly affected at first, suddenly underwent complete necrosis and the necrotic material filled the tubular spaces as a coarsely granular, almost hyaline mass. This marginal epithelium probably receives just sufficient nutrition by imbibition to keep it alive for a short time. When this nutrition fails, probably because of the pressure of the swelling infarct, the epithelium suddenly undergoes this peculiarly rapid necrosis.

In many of the infarcts, for the first twenty-four or forty-eight hours, a small number of tubules in the margin and, indeed, a few fairly deep in the infarct, retained their form and normal staining reactions, but at the end of this time, as the infarct became sharply defined, these tubules became less frequent and were very exceptional in older infarcts.

In the spleen, the degeneration of the cells of the pulp and follicles appeared first as nuclear pyknosis and fragmentation, which was especially evident in the center of the follicles. It extended rapidly, however, so as to involve the entire follicle and pulp. The protoplasm showed little demonstrable change until about forty-eight hours had elapsed, when there was distinct solution.

The interstitial tissue did not degenerate until late in the course of the condition. In the glomerular tufts necrosis was evident first in nuclear fragmentation and then in complete disappearance of nuclei and vascular loops. In the spleen, the trabeculæ lost their nuclei rather by lysis than by rhexis, and subsequently the whole mass of tissue lost its outlines.

Regeneration of the parenchyma in the kidney was evidenced only by the presence of mitotic figures, sometimes typical and sometimes atypical, in the tubules immediately surrounding the infarcted zone. In concordance with other workers, we were unable to demonstrate tubule formation. We were not able to demonstrate regenerative changes until a week had elapsed, and in the series in which artery, vein and ureteral circulation were cut off, the sections showed no mitoses whatever.

In the spleen, no evidence of regeneration was found. In both spleen and kidney, however, organization at the periphery of the infarcted areas was demonstrable at four days and was well under way at the end of one week. The newly-formed tissue in both organs was notably poor in new blood-vessels. In the kidney, variations in the growing connective tissue, under the differing circulatory conditions, was not noted.

In the series in which practically all the circulation was cut off, marked progressing fibrosis throughout the non-infarcted areas was present, but the growth immediately about the infarct was no greater than in the other series.

CONCLUSIONS

The most important conclusions are:

1. Regardless of general circulatory conditions, all infarcts of the kidney and spleen of the dog are first hyperemic, then hemorrhagic and finally become pale from coagulation necrosis.

2. The hyperemia of the early infarcts is, in a general way, proportional to the vascular pressure within the organ as a whole, and is not due to reflux of blood from the veins.

3. Conglutination of the red blood-corpuscles is the earliest demonstrable change in the blood of the infarct; removal of pigment from the infarcted area is probably due to plasmatic diffusion; definite fibrin formation appears relatively late in the course of the condition.

4. Necrosis progresses more rapidly in infarcts in those organs in which the general circulation is altered in some way (either from damming back of blood by vein ligation, or from cutting down arterial supply), than in organs in which the general circulation is normal.

5. The pallor of the white infarcts is due to decolorization of the contained conglutinated and coagulated blood; decolorization begins in a general way in the middle of the infarct and extends peripherally.

6. Organization progresses as well in organs in which the general circulation is diminished as in those in which the general circulation is normal.

7. Regeneration is seen, in the kidney, only in the occurrence of mitotic figures in the epithelium near the margin of the infarct; it is diminished by any decrease in the general circulation. Regeneration of the cells of the splenic pulp or follicles is not demonstrable previous to, or at the end of, one week.

THE IMPORTANCE OF MEDIASTINAL GLANDS

AND FAILURE TO MAKE PROPER DIAGNOSIS *

JAMES A. HONEIJ, M.D.
CAMBRIDGE, MASS.

This investigation, the results of which are shown below, was undertaken to determine the significance of mediastinal or bronchial glands in early or mistaken cases of tuberculosis of the right lung apex. Before considering the diagnosis of these glands and their connection with mistaken cases of right apical tuberculosis, it may be well, however, to examine anatomically the location of the bronchial glands and their relation to other lung structures and to review the literature on this subject.

As seen in the diagram (Fig. 1, Sukiennikow's[1]), the greater number of glands are situated on the right and along the main bronchial vessels; there is also greater massing of glands on the right as well as chain formation. Normally, we also find that the right bronchus branches off at a higher point than the left, corresponding to the fifth dorsal vertebra (Gray[2]); it is also shorter, wider and more vertical than the left bronchus. The right bronchus apparently is also a more direct continuation of the trachea than the left (Gray). Sukiennikow, describing the development of the tracheobronchial and the bronchopulmonary lymph-glands, concludes that the appearance and the grouping of these glands have a fixed regularity of massing, and that those situated in the angle of the bronchi are bound there. It is also well to remember that the cervical lymph-nodes are not anatomically connected with the tracheobronchial lymph-nodes (Bartel[3]), so that these glands are excluded from our consideration.

In 1889 Krönig practiced a method of percussion of the apices, which determined for him the existence of a simple non-tuberculous collapse induration of the right lung apex; and in 1907 he issued a treatise[4] wherein he set forth his studies regarding the false dulness obtained at the right lung apex, usually over the clavicle and spine which had a great similarity to incipient tuberculosis. Associated with this was a residual light bronchial catarrh, cough, expectoration, etc. His explanation was a physiologic one, namely, an impaired infiltration caused by adenoid growths and catarrhal mucous membranes, and that, with a greater inspiration of dust-laden air on the right, an induration resulted at the right apex and later a collapse of that portion. The bronchial breathing is slightly increased, but varies very little from the normal. In 1908 Blumel[5] substantiated these findings of Krönig. On the examination of 1,700 referred tuberculous patients, eighty-five did not have tuberculosis, and twenty-eight of these were considered as cases of collapse-induration. Wolff-Eisner,[6] in 1909, with the aid of conjunctival tuberculin reactions, demonstrated the same thing in several cases. Bing,[7] in 1910, in the examination of a great many cases by means of a sagittal method of percussion like Goldscheider's[8] found another cause for false dulness at the right apex. This dulness occurs in older children of tuberculous families. He found by percussion either a slight or an increased dulness, but with auscultation nothing very definite. These findings covered a much less surface than his cases of apical infiltration, and the harsh breathing usually found in such cases was virtually absent. On a closer examination and by lighter sagittal percussion with firm pleximeter pressure, especially in the intercostal spaces, which brings one closer to the lung, he concluded that he was dealing with enlarged bronchial glands. According to Bing, no cases were found of Krönig's retraction dulness, and he concludes that it should not be considered unless all evidence of adenopathy has been ruled out, and that wherever swelling of the bronchial glands occurs, there will be found a false dulness at the upper half of the right lung apex. This is slighter on the inner and greater on the outer side, thus differentiated from true infiltration dulness by position and by Goldscheider's method of sagittal percussion which emphasizes the median line and upper borders of the lung, front and back surfaces with the accompanying dulness over sternum and back. Bing's explanation includes the statement that by the swelling of the bronchial glands, more or less air-spaces are shut off, and that, as a result of this, dulness can also be demonstrated at the junction of the second rib and the sternum, along the right of the sternum, and at the back from the third to the sixth rib. Figure 2 is made from one of his cases.

Bing declares that should one percuss by Krönig's more or less vertical method, a clear sounding zone or isthmus would be found above the upper border of the lung. In disease processes this zone is decreased and the

percussion sound diminished, but if his method of sagittal percussion is used, no actual dulness is found, which is present only with the vertical method. It is apparent, therefore, that a dulness at the apex in the median line is due to an infiltration. If found more lateral and below the apex, in first or second intercostal space, by sagittal percussion, it is due to a more or less solid process occurring lower down in the lung. Consequently, it may be dependent on the swelling of glands and verified by dulness over the sternum at the first intercostal space. Some of Bing's cases were corroborated by x-ray examination. These findings do not apply to cases in which there is more muscular development on the right side or any other physical changes.

D'Espine,[9] in 1907, described an auscultation sign which some investigators claim of value, in determining the presence of tuberculous bronchial glands in children, namely, the whispered voice with a bronchial ring heard at the level of the spinous process of the seventh cervical vertebra and over the first dorsal vertebra. This, he explains, is due to the enlarged ganglions which surround the lower part of the trachea and the bifurcation of the bronchi. In a number of non-tuberculous cases (bronchopneumonia with measles and four cases of grip), the sound was present from the seventh cervical and over the first four dorsal vertebræ. Autopsy showed that in some cases adenopathy was present. He therefore emphasizes that where the sound persists for five or six months and longer, there can be no doubt of the presence of enlarged bronchial glands.

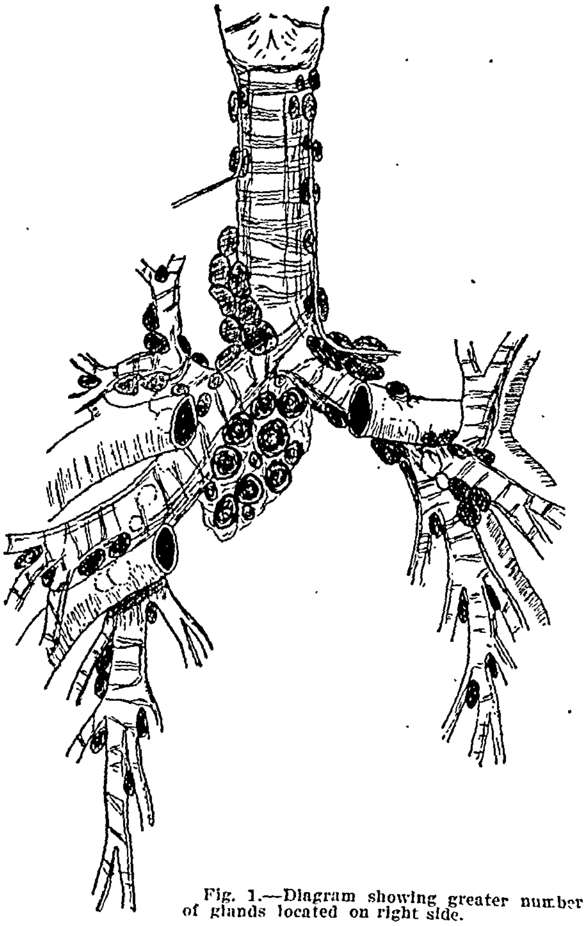

Fig. 1.—Diagram showing greater number of glands located on right side.

Gray, in 1908, found with auscultation according to D'Espine's method over the vertebral column the bronchial respiratory murmur. He emphasizes that in examining children in auscultation certain voices are husky and lacking in resonance owing to laryngeal disease and that other tracheal sounds may also predominate; but he does find that vertebræ auscultation offers certain almost constant findings. Sokolowski[10] has found in enlarged gland cases that the expiration is prolonged and more intense and inspiration rougher, especially between the shoulder blades. Stoll,[11] in the examination of 175 children for tuberculosis of the bronchial glands, obtained some results which, although not conclusive, are interesting. He found that dulness over the sternum or in the inner third of the first left intercostal space was present in forty-one cases, of which 49 per cent. reacted to tuberculin. On percussion of the vertebra spines, at or below the fifth dorsal, positive signs were present in nine out of forty cases; all nine reacted to tuberculin, and the seven adults, all of whom had other signs of bronchial gland enlargement, had either vertebral or paravertebral dulness. Vertebral bronchophony was present in eighty out of 168 children and sixty-six of the eighty reacted to tuberculin, and in twenty-four adults who had vertebral bronchophony 80 per cent. gave positive tuberculin reaction. Roberts[12] says that in a fair proportion of cases glands do not give rise to any symptoms or they may be obscured by existing lung trouble, but when the bronchial glands are affected and attain a sufficient size, the character of the breathing and cough will reveal more or less obstruction of the main air passages or nerve irritation; and it is to the phenomena thus originated that special attention must be paid

in early diagnosis, particularly in children. Numerous other signs, such as enlargement of the veins of the chest, pains, hiccough, cough, etc., are fully mentioned in literature (Sahli,[13] Osler,[14] Roberts, and others), but, in the opinion of investigators, they are secondary considerations to auscultation and percussion. It is apparent, however, from the foregoing that when the tracheovertebral and bronchovertebral spaces are occupied by glands, they may then become sound transmitting. When on examination the patient bends forward, the structures are in close proximity to the vertebral column and on auscultation and percussion disease conditions are more easily determined. It is also clear, from an anatomic-physiologic point of view, that if inflammatory conditions or pressure are present on the bronchi, the right lung and apex would more easily convey any abnormal sound that is produced.

TUBERCULIN REACTION

In the past few years discussion has been caused by the fact that tuberculosis reactions were obtained in so-called negative tuberculosis cases. Hamman and Wolman[15] reported that in non-tuberculous cases, 57 per cent. reacted to the skin tuberculin test and 83 per cent. reacted in the doubtful cases. In seventy-seven cases of Stoll's, 57 per cent. reacted to tuberculin, and in sixty-nine cases not classified 32 per cent. gave reactions. These were from a total of 175 children whom he studied to prove the reliability of certain signs said to be indicative of tuberculosis of the endothoracic glands. Sachs[16] concludes, in discussing the value of local tuberculin reactions, that the verdict of to-day is that a positive reaction following the local application of tuberculin signifies the existence of a tuberculous focus somewhere in the organism, without giving a definite idea of the active or latent character of the process. It will be sufficiently plausible, then, to suggest that a great many patients may have had tuberculous thoracic glands.

Pathologically, it is obvious that in considering enlarged glands which occur in the chest we are dealing with no one disease class. In all likelihood, tuberculosis is in the majority of cases responsible for their enlargement. But the glands alone may be involved, either in an acute or subacute stage, or inflammation of neighboring structures may have been extended to them. The tracheobronchial or mediastinal glands act as filters in which lodge the various foreign particles which escape the normal phagocytes of bronchi and lungs (Osler). It has been pointed out by various writers that catarrh of the mucous membranes predisposes to disease of the mediastinal glands. The lymph tissues and possibly the tonsils are so impaired that the bacteria find their way down until taken up by the lymphatic glands. Should spontaneous healing not take place, which Osler states happens too often, acute tuberculosis results. These glands may enlarge to such an extent that they produce pressure symptoms (Osler, Roberts, Sokolowski and others). The bronchi, and especially the right bronchus, may be compressed to such a degree that abnormal breathing sounds are caused, which may arouse suspicions of apical tuberculosis. Other symptoms, of course, may arise and in one case examined at the City Hospital there was reason to believe that pressure on the esophagus, giving rise to stricture signs, was due to enlarged mediastinal glands (Osler). Suppuration of the glands and perforation of adjacent vessels is not uncommon (Sokolowski). Abscess may occur (Hare[17]) and is not uncommon. It was found in a collection of mediastinal disease cases that the anterior mediastinum was far more frequently affected than the other two spaces and that the disease, whatever it may be, occurs more among males than females (Roberts, Hare). In a list of nonsuppurative mediastinitis Hare gives only two cases in which the glands were affected, one occurring in the middle and the other in the posterior mediastinum; this was from a total of sixteen cases. Of 104 cases of miscellaneous diseases of the mediastinum, fifteen cases were of glands.

The question of tuberculosis of the glands and whether primarily infected has been broadly argued by most pathologists. Wollstein,[18] in a study of the distribution of the tuberculous lesions in 185 infants and young children (post mortem) under 3 years of age, showed that 16.4 per cent. gave tuberculosis of one or more organs. In thirteen cases the lungs and bronchial nodes were alone involved and in one case the bronchial lymph-nodes were alone involved; this was at the root of the right lung.

Considering the bronchial nodes alone, there occurred in 131 cases tubercles with cheesy degeneration, in three cases suppuration and in six cases calcareous degeneration. In thirty-eight cases the mediastinal lymph-nodes were markedly affected.

What is especially interesting for consideration is that ninety-seven cases gave the largest bronchial lymph-nodes on the right side, compared with thirty-four cases on the left side. This is naturally explained by the previously stated fact that the right main bronchus is shorter and wider and a more direct continuation of the trachea, so that inspiration is facilitated in the right lung. There appears to be no question as to the primary affection of the glands (Roberts), but whether any previous disease predisposes to this is to be considered, and Roberts states that it is a question whether these glands are contracted glands of a previous disease or the early affection of a present disease. He also believes that heredity is a factor in primary tuberculosis of the glands.

Tendeloo, in his article on the channels of infection,[19] decidedly states that if there is tuberculosis of the bronchial lymphatic glands without tuberculosis elsewhere, it has occurred from the bacilli coming from the lung. He also states that the primary tuberculosis foci occur not in the apex but near the apex and the vertebral column. He more precisely says that the primary foci occur most in the peribronchial, perivascular tissue, concluding, however, that it is possible that bacilli go from the pulmonary lymphatics either directly or after having infected one or more peribronchial lymphatic glands, then from these glands elsewhere in the lung lymphatics. Hare's statement is that the tubercles may arise in the glands themselves, or become secondary growths, owing to primary disease of the lung or pleura, and in many cases at the post-mortem the tubercular involvement is so general that it is impossible to decide as to the primary seat.

In 151 cases of healed tuberculosis (Adami and McCrae[20]), the thoracic glands were involved in forty-five cases and in these the group of glands at the lung root predominated thirty-eight times, and where only a single site was found it was twenty-three times in the lung root group. In the latent tuberculosis cases (93), the thoracic nodes were involved thirty-five times and eighteen times in combination with disease of the lungs. The relation of pleural adhesions to healed and latent tuberculosis gave eleven cases in which tuberculosis existed in the thoracic nodes and six in combination with disease of the lungs.

[20] Adami and McCrea: Tr. Sixth Internat. Cong. Tuberc., 1905, i, 325.

In considering the sites of early tuberculosis infection, Adami and McCrae show that the thoracic nodes were affected in 33 per cent., which is second to the lungs in frequency of infection. In another group of generalized tuberculosis the figures are still more interesting from our point of view, in that the lungs were involved only in 14 per cent. more (that is, in 95 per cent.) than in the lymph-nodes which showed 81 per cent., or thirty-five cases; of this number all but two cases were in the glands of the thorax. In connection with, and under the head of, tuberculous infection of other organs, there are forty cases given of involvement of the thoracic nodes.

From the foregoing figures it can, therefore, be accepted that tuberculosis of the thoracic lymph-nodes occurs next in frequency to tuberculosis of the lungs, and that the disease does occur alone in these glands. It is also consistent to say that since there are more glands on the right side and since physiologically or anatomically the structural position of the bronchi is such that disease in aspirated infection is more likely to occur on that side, there is all the more reason to believe that tuberculosis of the right bronchial or peribronchial lymph-nodes can be confused with the diagnosis of tuberculosis of the right apex. This contention, that many cases of questionable tuberculosis of the right apex is due to disease in the glands, is strengthened if Adami and McCrae's findings are accepted—that tuberculosis does not occur more often in the right apex—and also Krönig's reports on *Collaps-Induratic* of the right apex in which the symptoms closely resemble those of early infiltration. Bing also emphasizes the difference between early tuberculosis of the right apex and the enlargement of thoracic glands. Sokolowski states that the enlarged glands are mostly found post mortem and as such have little significance.

RESULTS OF INVESTIGATION

The physical and fluoroscopic examination of the chests of 620 patients at the Boston City Hospital has demonstrated the common failure to recognize accurately the presence of mediastinal or bronchial glands. The majority of these patients were referred to the *x*-ray department to ascertain or verify the presence of tuberculosis of the lungs. In the light of recent statements made concerning the percussion dulness found at the right lung apex (Krönig, Bing), the results shown in the accompanying tables may be interesting.

Of these 620 patients examined by fluoroscope, 147 showed the presence of glands in the mediastinum or at the root of the lungs. The majority, as stated, were either tuberculous or had signs in the chest which were thought might be tuberculosis; most patients had several physical examinations. Of these 147 patients, in only two did the question arise of the probability of enlarged bronchial or posttracheal lymph-glands.

It is conceded that in most of these cases the glands were not large enough to cause marked disturbances, but considering that there were a number of cases of questionable right apical tuberculosis, one may presume that in the cases proving negative by fluoroscope, the glands may have given rise to the signs which were interpreted as early apical tuberculosis.

In a large number of early apical tuberculosis cases examined at the Boston City Hospital and at the Boston Consumptives Hospital it was noted that a certain percentage proved negative, while among these patients, the majority of whom were children, many reacted to tuberculin. There was no idea at that time of examining for thoracic glands, but as a result of this interesting study the indefinite thought occurred whether enlarged glands by pressure or otherwise might not be the cause of the questionable dulness at the right apex, with the sharp or rough inspiration, etc. Since then definite statements

have been made, as already quoted, by Bing and others that dulness at the right apex can be caused by the swelling of bronchial glands.

In 100 cases of this investigation of questionable tuberculosis, it was shown that in fifteen there was no tuberculosis and of twenty-four diagnosed as tuberculosis, seventeen proved negative. In these thirty-two negative patients the glands were shown to be enlarged. In eighty patients of 100 diagnosed as questionable and in twenty-four diagnosed as positive cases the apices were the parts under consideration. Of the eighty, the right apex was questioned in thirty-two, the left in eight and both in forty cases. In five cases of enlarged questionable aneurysm of the aorta, there proved to be enlarged glands present and no aneurysm. Therefore, we have apparently found dulness in a number of cases at the apices and especially at the right apex where no congestion or infiltration was found, but where enlarged thoracic or bronchial glands were evident. Considering that of 147 patients with questionable or positive cases of tuberculosis or other diseases, there were glands on the right side in fifty, on the left in seventeen, on both sides in forty-four and in the mediastinum—that is glands above the roots of the lungs—in thirty-six cases, we can state that glands do occur more often on the right side than on the left and in conjunction with the right apex dulness. In the examination of these cases it was difficult to determine the presence of glands or their number when there was either tuberculosis, congestion or some such disease extending over a great part of the chest and consequently overshadowing the glands. It does not, therefore, follow that when glands have been seen on the left side, and not on the right, that they may not, however, be present there also. It is a question also whether the statement which Bing makes that bronchial glands occur mostly in young children is absolutely correct. In this series of cases, 118 patients were adults, that is, above 20 years of age. It is a more difficult matter to percuss an adult chest for bronchial glands than a child's. In the adult chest we must take into account development due to occupation, habits, etc. On the other hand, children show a so-called physiologic dulness at the right apex which may prejudice one in favor of bronchial glands. In fluoroscopic examinations a child's chest gives a greater opportunity to discover bronchial glands than an adult's. Still, of 145 patients, only twenty-seven with thoracic glands were below 20 years of age. Another group of cases, which is not included in this present paper, but which may have bearing on the consideration of bronchial or mediastinal glands, is that in which there is obscurity of the space behind the heart and aortic vessels. On account of the more questionable nature of this obscurity, these cases were not investigated.

Sukiennikow states that the prevailing position of the lymph glands is anterolateral, especially the tracheobronchial group, and gives this as a reason for the difficulty that is encountered in diagnosing them, when enlarged, by percussion. Osler's statement is broader still. He says that unless the glands are large enough to cause compression of lung tissue, he doubts whether the ordinary bronchial adenopathy ever can be determined by percussion in the upper interscapular region.

One other difficulty was the inability to tell in certain obscure cases whether a gland was single or whether two or three were adherent. From our anatomic knowledge, it is very likely that in the case of bronchial glands there were several instead of one.

Usually, where the glands appeared on both sides the apices were also affected, and in a large number of questionable cases of tuberculosis the glands were either single or on one side.

The conclusion is that in a number of cases the glands were enlarged where tuberculosis was either not present or suspected, and were of sufficient importance to either produce certain physical signs confused with tuberculosis or were the probable cause of a tuberculin reaction.

CONCLUSIONS

1. Enlarged glands occur more frequently on the right side than on the left.
2. Enlarged glands may cause the signs which are often considered as those of early apical tuberculosis. This has been explained in anatomic and physiologic terms.
3. Enlarged glands occur in both tuberculous and nontuberculous patients and probably occur as frequently in adults as in children.
4. Positive tuberculin reactions may, therefore, in negative tuberculous cases, be due to enlarged glands in the mediastinum, etc., when apical signs are not present.
5. The results of this investigation demonstrate the common failure to diagnose the presence of mediastinal or bronchial glands, and show the importance of emphasizing the more careful examination of so-called early tuberculosis cases.

IMPROVED TECHNIC OF THE THIERSCH GRAFT FOLLOWING THE RADICAL EAR OPERATION *

CULLEN F. WELTY, M.D.
Surgeon Chief of Otology, San Francisco Polyclinic; Otologic, Rhinologic and Laryngologic Surgeon, St. Mary's Hospital and City and County Hospital; Consulting Otologic, Rhinologic and Laryngologic Surgeon, German Hospital,
SAN FRANCISCO

In the preliminary report of the improved technic of the Thiersch graft following the radical mastoid operation,[1] I reported a series of eighteen cases, in which graft was applied four days following operation, and said that never before had such a series of cases been brought to healing in such a short time and that never before had the hearing been so uniformly good (Table 1).

I shall here report a series of twelve cases in which I operated. Graft was applied at the time of operation. This report will be even better than the former, besides eliminating a second operation that consumes almost as much time as the original mastoid operation, while the original operation is only lengthened about fifteen minutes. This of itself, I consider a great boon for the procedure; in fact, it makes the radical ear operation a simple, concise and precise operative procedure, attended with no risk to life whatsoever, providing the cochlea and canals are intact (Table 2).

The further improvement of the technic will consist in a more thorough removal of the mucous membrane of the tube, the mucous membrane of the inferior part of

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Ann. Otol., Rhinol. and Laryngol., March, 1911.

the tympanic cavity, and the cutting away of the inferior bony meatus, so that it is absolutely on a plane with the floor of the tympanic cavity. I shall repeat the detailed technic of this operative procedure.

Every individual cell is destroyed until hard bone is encountered, or the dura, sinus or nerve uncovered. This final destruction of cancelous bone is best accomplished by me with a hand burr; it can be done with a burr driven by electricity, however, I prefer such burr for the bone of greater density. It is very essential that all the uneven surfaces be made perfectly smooth.

The outer part of the bony meatus must be removed sufficiently to be on a horizontal plane with the floor of the tympanic cavity. The posterior bony wall must be cut down to the floor of the newly-made bony meatus. By this procedure more room is gained and the pocket which was formed by the tympanic cavity has been eliminated. In the removal of the posterior bony meatus and facial spur, great care must be exercised in not injuring the facial nerve. This is best avoided by chiseling the wall away with large chisels and working parallel to the nerve, so that in the event that the nerve is uncovered, it would not be cut. This particular point will enable the operator to remove more bone than any other with more safety to the facial; in fact, the facial will not be cut by an experienced operator.

TABLE 1.—EIGHTEEN CASES OF RADICAL EAR OPERATION BY IMPROVED THIERSCH GRAFT

Case No.	Age	Sex	Discharge	Operative Findings	Hearing Before and After Operation: Before	After	Duration of After-Treatment (weeks)*
104	26	F.	Childhood.	Cholesteatoma.	Whisper, 6 ins.	Whisper, 6 ft.	Six.
105	14	M.	Two yrs.	Cholesteatoma.	Speech, water, 6 ft.	Speech, water, 15 ft.	Four.
107	28	M.	Childhood.	Cholesteatoma.	Whisper, 3 ft.	Whisper, 3 ft.	Six.
108	19	F.	Childhood.	Cholesteatoma.	Whis'r, water, 12 ft.	Whis'r, water, 26 ft.	Four.
109	10	M.	Childhood.	Cholesteatoma.	Whisper, 1 ft.	Whisper, 26 ft.	Four.
110	14	M.	Childhood.	Cholesteatoma.	Whisper, 1 ft.	Whisper, 25 ft.	Four.
111	25	M.	Two yrs.	Cholesteatoma.	Whis'r, paper, 3 ins.	Whisper, 6 ft.	Six.
113	33	F.	Childhood.	Cholesteatoma.	Whis'r, paper, 3 ft.	Whis'r, paper, 20 ft.	Three.
115	26	M.	One yr.	Cholesteatoma.	Whis'r, paper, 15 ft.	Whis'r, paper, 26 ft.	Four.
117	16	M.	Childhood.	Caries.	Whis'r, paper, 1 ft.	Whis'r, paper, 6 ft.	Four.
118	12	M.	Five yrs.	Caries.	Speech, 3 ft.	Whis'r, chair, 25 ft.	Three.
119	16	M.	Two yrs.	Caries.	Whisper, 25 ft.	Whisper, 3 ft.	Four.
120	9	M.	Seven yrs.	Cholesteatoma.	Whisper, 1 ft.	Whisper, 6 ft.	Three.
121	29	F.	Childhood.	Caries.	Whisper, 6 ins.	Speech, 1 ft.	Three.
122	29	F.	Childhood.	Caries.	Whisper, 3 ft.	Speech, 3 ft.	Four.
123	4	F.	Three and one-half yrs.	Cholesteatoma.		Good.	Four.
124	30	M.	Childhood.	Cholesteatoma.	Whis'r, chair, 2 ft.	Whis'r, chair, 15 ft.	Five.
125	18	F.	Ten yrs.	Cholesteatoma.	Speech, 2 ft.	Whisper, 25 ft.	Four.

Duration of after-treatment:

In 4 cases 3 weeks.
In 10 cases 4 weeks.
In 1 case 5 weeks.
In 3 cases 6 weeks.

Hearing, following operation, for whisper:

In 6 cases 25 feet or more.
In 3 cases 15 feet or more.
In 3 cases 6 feet.
In 2 remained the same.
In 1 case could not be measured, but good.

* The duration of the after-treatment dates from the day of the radical mastoid operation and not from the day of the graft, which was four days later.

TABLE 2.—TWELVE CASES OF RADICAL EAR OPERATION

Case No.	Age	Sex	Duration	Operative Findings.	Hearing: Before	After	Duration of After-Treatment (weeks)
127	21	M.	Childhood.	Caries.	Whisper.	Improved.	Three.
128	21	M.	Childhood.	Caries.	Whisper, 3 ft.	Improved.	Two.
129	31	M.	Childhood.	Caries.	Whisper, 6 ins.	Whisper, 25 ft.	Ten.
130	38	M.	Five yrs.	Caries.	Whisper, 6 ins.	Whisper, 18 ft.	Six.
131	20	F.	Childhood.	Caries.	Whisper, 3 ins.	Remnants.	Four.
132	46	M.	Childhood.	Caries.	Whisper, 2 ins.	Whisper, 15 ft.	Four.
133	34	F.	Fourteen yrs.	Negative.	Whisper, 3 ft.	Whisper, 26 ft.	Three and one-half.
134	17	M.	Eight yrs.	Caries.	Whisper, 6 ins.	Whisper, 6 ft.	Three and one-quar.
135	9	M.	Three yrs.	Caries.	Whisper, 1 in.	Whisper, 4 ft.	Three and one-half.
136	7	F.	Infancy.	Caries.	Whisper, 3 ft.	Whisper, 25 ft.	Four.
137	17	M.	One yr.	Caries.	Whisper, 6 ft.	Whisper, 26 ft.	Three.
138	9	M.	Childhood.	Caries.	Whisper, 3 ft.	Not made.	Three.

The mucous membrane of the tympanic cavity must be entirely removed. I literally mean that after a very thorough inspection, none can be detected, at this place it will be necessary in most cases to use a hemostatic agent of some kind, as hot saline solution, hydrogen peroxid or epinephrin. Most careful attention must be directed to the tube in order to remove the mucous membrane thoroughly.

The tympanic wall should be so thoroughly removed by chisel and made smooth by burrs, so that the small searchers of Jansen's will not be arrested.

Everything said so far, while absolutely important in every radical operation, is much more important when Thiersch grafts are to be applied, as any infection that may remain in the bone will ultimately destroy the graft and one will fail to accomplish what he set out to do.

The Neumann plastic should be made in preference to all others for this particular procedure, the upper and lower flap sutured in place and the point of the V sutured to the auricle. The sutures to be used in holding the V part of the plastic should be catgut. The sutures for the upper and lower flap had better be catgut, as the use of other sutures, if allowed to remain, may or may not cause trouble in the after treatment of the case.

At this time I use hot saline solution as a hemostatic agent inspecting the cavity from time to time; finally, to reassure myself, I use peroxid of hydrogen several times. When I am satisfied beyond a question of doubt that everything is away, I put in gauze saturated with epinephrin (P. D. & Co.), this gauze is held in the cavity under pressure by an assistant, while the grafts are being prepared. At the time I begin my preparation of the ear plastic, the nurses are preparing the leg or part from which the grafts are to be taken. In this preparation, mercury bichlorid has never been used. Sterile salt solution used in excess, following all the other aseptic procedures.

I try to get about three or four grafts ½ inch wide by 1½ inches long, and some smaller ones, ¼ inch by ½ inch. Some of the grafts may be lost in preparation or in applying them.

The Jansen spatula is used, grafts are taken from the razor directly to the spatula, all edges straightened and put aside for use. When grafts are in readiness the epinephrin tampon is removed from the ear. The cavity will be found to be absolutely dry and if not, more epinephrin must be used; the cavity must be free from oozing blood or the grafts will not adhere.

The first graft is fastened with a searcher into the tube, bringing it out over the floor of the tympanic cavity posteriorly; second superior to the first, brought back over facial into mastoid cavity. The third usually covers the remaining wall of the attic and antrum. The three which have been used are the larger ones. The uncovered areas that are left are covered by the remaining grafts, the one being selected that will cover the denuded area best. Small pledgets of cotton are now used to fix the grafts; they must be so small that they do not touch either surface while being put in place The first one is put over and into the tube, the second firmly applied to the posterior inferior quadrant, the next over the stapes and so on until all the grafts are held well in place, so they will not be materially disturbed when a dry tampon is introduced. The size of this tampon will correspond to a piece of gauze 2 or 4 inches square. After the dry gauze, a similar piece of gauze is saturated with 0.5 per cent. solution of phenol (carbolic acid) in paraffin oil, U. S. P. (especially sterilized in 10 c.c. ampoules),[1] and packed within the mastoid cavity; after this a similar piece, larger or smaller as the occasion may demand, is used to fill the entire cavity made by the operation. The posterior wound is now closed in the usual manner. It will be found that an additional tampon by way of the meatus will assist materially in holding the plastic in the way intended, resulting in a very large meatus with cut surfaces all within the ear. This materially adds to the comfort of the patient, as well as preventing a contracted meatus. The usual outside dressing is used. The ear tampons are removed on the fourth day. If there is any difficulty or pain in the removal of the tampons, contrary to the ordinary teachings, hydrogen peroxid can be used in excess to soften and loosen them; this procedure will also aid in getting rid of the blood and stop bleeding, so that the small cotton fasteners that were put in to hold the grafts in place can be seen and taken away. I wish to add that it is quite important to know the number of small cotton balls that have been put in the ear to hold the grafts, otherwise one may be left which will cause trouble sooner or later.

In 50 per cent. of the cases one will look into a white cavity; in fact, all of them are white if one takes the time to stop the bleeding that comes from the inner surface of the soft parts which have been sutured and could not be covered with graft.

This is the improved technic of the Thiersch graft in the radical ear operation.

In fact, a graft never adheres to the tampons to be torn from its attachments. In some of the cases, the outer layer of epidermis will loosen in ten days or two weeks after they have been applied; they will always leave a delicate epidermis that will harden in a very short time. I hardly know how to account for the fact that, in some cases, the entire graft remains in place, while in others the outer layer comes away. The only explanation that I can offer is that, in some instances, the graft is too thick. This does not seem to be serious, however, as the cases heal in about the same time. Occasionally it will happen that granulation tissue makes its appearance when the edges of the graft are not in perfect apposition. They are very easily destroyed with the ring knife. At the following dressing, the denuded area will be completely dermatized.

Occasionally, excessive granulation tissue makes its appearance in the region of the plastic. This is removed with curet and packed tight with gauze saturated with sterile liquid petrolatum. Contrary to the teachings of to-day, bichlorid of mercury is used to irrigate the cavity. This is necessary where there is an unusual amount of pus or odor from secretion. In other instances where there is more debris than should be, I always irrigate with the intratympanic cannula and under inspection, so that the force of the stream is directed to the particular spot that requires attention. I also irrigate with normal salt solution and boracic acid.

As has been said before, the oil dressing is removed in four days, or sooner if necessary. In two days a second dressing is made which includes an irrigation of bichlorid of mercury, 1-3000, and from this on, dressed daily until complete recovery. The particular reason for the bichlorid at the second dressing is to remove disagreeable odor, debris, or to see with more accuracy that all the cotton tampons have been removed.

The final procedure of every dressing is a thorough drying of the ear. After this, pulverized boracic acid is blown into the ear, single small pieces of gauze, ½ inch square, introduced into the ear, with a small roll of gauze fitting snugly into the outer meatus. As a rule, the bandage is left off in from ten to twelve days after the operation.

The majority of this series of twelve cases have been more or less complicated because of prior operations or existing labyrinth complications that added somewhat to the risk of operation. Some of the cases are quite out of the ordinary. In many of the cases, healthy dura was uncovered by the chisel and grafts used as described. In two instances dura with a granulating surface presented, the grafts covered everything but the granulating surface of the dura.

In conclusion, I wish to state that all cases of chronic suppurative otitis media (chronic after one year duration, nose and throat in order) are dangerous to the individual; all patients should be operated on, and all will recover if properly operated.

Second, the hearing will be improved in all cases, providing that the internal ear is intact as shown by the tuning fork examination.

Third, there is no danger associated with the operation provided that the labyrinth is intact. This latter statement is based on approximately two hundred radical mastoid operations.

CASE REPORTS

CASE 127.—*Patient.*—A man, aged 21, a laborer, had had discharge from the right ear since childhood. At the age of 15 the ear was operated for the first time, and he had three different operations since. He came to me with an acute exacerbation of a chronic suppuration, pain over the whole side of the head, especially over tip of the mastoid. For three weeks previously he had had repeated attacks of vertigo.

Examination.—Head on diseased side was sensitive to touch and especially over the tip of the mastoid. Temperature 101 F., surface temperature of mastoid more than that of other side. The mastoid cavity was filled with connective tissue, foul smelling pus and debris; denuded bone detected by a probe. Patient could not hear whisper, except with the 7-foot hearing-tube. Weber to the opposite side. C^1, C, c^4, all negative. Watch on bone, negative. Neumann's alarm apparatus, positive. Intense vertigo, tinnitus, spontaneous nystagmus to the opposite side. Caloric reaction, positive; the cold water was continued for quite a while before the nystagmus was increased. Fistula symptom, negative. From the findings it must be concluded that the cochlea and canals were intact.

Operative Findings.—Large mass of organized connective tissue filling the greater part of the cavity made by previous mastoid operations. The whole tip of the mastoid was carious, caries of the zygomatic cells, as well as the overhanging walls of the attic and antrum. My findings offer evidence that the last radical mastoid operation was not sufficiently complete to hope for a cure. Neumann plastic, grafts applied in the usual way. Dressing removed in six days, every graft adherent. Eleven days after operation every graft came away, leaving a very delicate epidermis which became white in a very short time. Between the grafts were small granulating areas that were covered in a few days by epithelium from the graft.

This patient was practically well two weeks after operation; however, there was a serous discharge that continued for a few days longer. I think this discharge was due to the sensitiveness of the new epidermis.

Hearing improved, absolutely dry in three weeks.

Case 128.—*Patient.*—A man, aged 21, laborer, had had a discharge from ear since childhood, and had three mastoid operations, the ear always having discharged. About one week before I saw him, he began to complain of pain over the whole side of the head, and had such intense vertigo that he had fallen in the street three times during the last week.

Examination.—The whole side of head painful to pressure, extremely painful over tip of mastoid. Temperature 100 F.; surface temperature of the mastoid increased over the other side. Scar of previous operation; foul, offensive discharge, large mass of organized connective tissue, uncovered bone discovered by a probe. Weber to diseased ear. Whisper (paper), 3 feet. Rinné, negative. Schwabach shortened. Negative for low forks, positive for high. Watch on bone, positive. Vertigo. No spontaneous nystagmus. Caloric reaction positive, very much exaggerated with only a small amount of water (hypersensitive). Fistula symptom, negative.

Operative Findings.—Overhanging attic and antrum walls carious. Polypi in antrum, horizontal canal stood out quite prominently; considerable of the bone about it had been destroyed by caries; large amount of connective tissue and additional caries of the tip of mastoid.

Neumann plastic, grafts; cavity dressed in five days, all grafts found adherent. Eight days after operation one graft came away, leaving a delicate pinkish-white epidermis. Case entirely dry fifteen days following operation. Hearing improved—as to how much I cannot say, because the patient left the city during the next few days without my permission.

I attribute the rapid healing in these two cases to the fact that the patients had been operated on before and were not cured; from this fact the bone was oversupplied with blood which in turn nourished the grafts very quickly.

Case 129.—*Patient.*—A man aged 31, capitalist, whose ears had been discharging since childhood, during the year previous to operation had felt pain back of right ear, with increasing severity. For the last three years he had had headache on diseased side of the head; during the last three months, vertigo following headache had kept him in bed for twelve hours at a stretch. During this time he had been taken home in a conveyance repeatedly, because of intense vertigo. The patient said that the pictures on the wall would jump; when eyes were closed he would feel the eyes jumping.

Examination.—Sensitive over tip of mastoid; entire destruction of drug membrane; hypertrophied tissue covering promontory; no great amount of pus, not much odor. Whisper, 6 inches. Weber to this ear. Rinné, negative. Schwabach, short. C^1, positive. C, negative. c^4, positive. Watch on bone, positive. Vertigo and tinnitus, spontaneous nystagmus, negative. Caloric reaction, positive (hypersensitive). Fistula symptom, negative.

Operative Findings.—Former fracture across mastoid and into attic and antral wall, making same irregular. This does not appear in the history at all (confirmed later by question). Sclerosed mastoid, sinus well forward, dura size of quarter uncovered. Facial uncovered by caries, horizontal canal stood out quite prominently surrounded by spicules of carious bone, caries being very deep posteriorly. Neumann plastic and primary graft.

Following operation the patient had considerable vertigo, nystagmus and headache; in fact he was not quite free from it until the primary dressings were removed which was on the sixth day. All grafts were intact. Fourteen days after operation graft over exposed dura came away leaving the characteristic pinkish-white appearance; no vertigo, nystagmus or headache at this time. About ten days following operation a granulation appeared posteriorly, just under the facial nerve, on more careful investigation a fistula was found that was quite deep, this was repeatedly curetted and touched with silver nitrate in substance until it finally healed in ten weeks. The ear was entirely epidermized at the end of three weeks with the exception of the fistula; the hearing at that time had been increased from a whisper at 6 inches to a whisper at 25 feet. The hearing at the time he was declared well was 25 feet.

I mention this case more or less in detail to show why it required so long to heal. Had I been sufficiently careful to find this fistula, the patient would have been entirely well in three weeks. It accentuates the very points I wish to emphasize, namely, that complete search must be made, and so long as the Jansen sound is arrested the operation is not complete.

Case 130.—*Patient.*—A man, aged 38, laborer, had had intermittent discharge from the ear for the last three years; three weeks before operation he began to have pain in the ear and had frequent dizzy spells, though he never fell. A swelling appeared below mastoid about one week before I saw patient.

Examination.—No pain on pressure or percussion. Swelling below tip of mastoid (Bezoldt's mastoiditis), large granulating mass was filling up meatus; offensive discharge. Whisper 6 inches. Weber to both ears. Rinné, negative. No spontaneous nystagmus. Caloric reaction, positive.

Operative Findings.—Sclerosed mastoid; small blackened areas throughout his sclerosed mass of bone; dura uncovered. From the abscess cavity the whole tip could be outlined. Neumann plastic. graft. Hearing before, whisper 6 inches; after, 18 feet.

I cannot say why healing was so slow in this case.

Case 131.—*Patient.*—A woman, aged 20, stenographer, had had discharge from the ear since childhood, and repeated attacks of facial erysipelas; also repeated attacks of vertigo for several years past.

Examination.—No pain or sensitiveness on pressure or percussion; entire destruction of membranum tympani; small granulation protruding from attic. Whisper, 3 inches. Weber to opposite ear (marked adhesive process in the other ear). Rinné, negative. C^1, positive. C, negative. c^4 positive. Watch on bone, positive. Vertigo, positive. Tinnitus, positive. Spontaneous nystagmus, negative. Caloric reaction, positive. Hearing 7-foot tube, whisper positive.

Operative Findings.—Caries of attic and antrum; dura uncovered, the size of two thumb-nails. Fistula of the oval window with a blackened margin about it, which demonstrates that it has existed for some time; a good-sized probe was introduced into the fistula. Neumann plastic, grafts in usual manner and closed.

First day after operation, everything satisfactory; second day, some vertigo. Third day, vertigo, nystagmus to the opposite side, vomited five times. Fourth day, dressing removed, not so much nystagmus, patient vomited twice. Grafts all adherent.

During the four days, the patient had no fever, the vertigo and nystagmus disappeared gradually. The patient left the hospital in ten days, well in twenty-eight days.

Observations.—My only careful examination of this patient was made nine months prior to operation. From the examination as made at that time, the cochlea and canals were intact, so that a radical ear operation would not have been attended with risk to the patient's life; but when I found a fistula and an old one at that, I felt sure there would be induced an acute exacerbation of the old labyrinth suppuration. However, the patient made an uninterrupted recovery. This patient should have had an operation on the labyrinth at the time of the ear operation, or no operation at all.

I relate this case in detail to accentuate the importance of repeated examinations, should the case not be operated within a few days.

At the time of examination the patient heard a whisper 3 inches; this was much reduced because of the opening of the vestibule. She still hears on this side but it is of no practical use. Had my labyrinth instruments been accessible, I would have destroyed the labyrinth at once; as they were not, I concluded the operation with a skin-graft. The patient made a good recovery which can be attributed to good luck rather than to modern otology.

Case 132.—*Patient.*—A man, aged 46, a structural iron worker, had had discharge from both ears since childhood, had had pain repeatedly back of the ear, on both sides; attacks of vertigo increasing in frequency.

Examination.—Tenderness over the whole side of the head, especially over the mastoid, exquisitely sensitive over the tip. Temperature 101 F. Increased surface temperature of mastoid when compared with the other side. Pupils widely dilated and sluggish. The ear was filled with a mass of granulation tissue, foul discharge. Whisper, 2 inches. Weber to bad ear. Rinné, negative. Schwabach, normal. C^1, positive. C, negative. c^4, negative. Watch on bone, positive. Vertigo and tinnitus, positive. Spontaneous nystagmus, negative. Caloric reaction, positive. Fistula symptom, negative. Seven-foot hearing-tube whisper, positive.

Operative Findings.—Sclerosed mastoid, caries of attic and antral walls. Neumann plastic, graft and closed.

Remarks.—Skin-graft spatulæ were forgotten and I applied the grafts from surface of round chisels. Patient entirely well twenty-eight days after operation. Whisper before operation 2 inches, after, 15 feet.

Case 133.—*Patient.*—A woman, aged 34, was hooked by a cow when 3 years of age; the ear and scalp were severely injured. The ear discharged from this time for fourteen years, since this; two or three times a year it discharged for a day or two. Never had pain back of the ear or in the ear. When the ear stopped discharging, seventeen years ago, she began to have vertigo which lasted for some two years. There was no vertigo for a period of four or five years. Since that time there had been more or less at intervals, lasting as long as five days. For the last year she had scarcely been free from vertigo; there had been so much and it had been so severe that it has incapacitated her as a housewife. At times so dizzy she would fall; vertigo and attacks of vomiting which have lasted for several days. Intermittent tinnitus began at 14, for the last year preceding operation it was so severe that it annoyed patient very much, at times explosive in character.

Examination.—Marks of injury about ear and scalp, not sensitive to deep pressure or percussion. Drum membrane intact, hammer very much retracted, membrane shows marks of previous suppuration. Whisper, 3 feet. Weber to diseased ear. Rinné, negative. C^1, positive. C, positive. c^4, positive. Watch on bone, positive. Vertigo and tinnitus as described in history. Spontaneous nystagmus to the opposite side. Caloric reaction, positive. Equilibrium disturbances, positive. Fistula symptom, negative.

Conclusions.—From the fact that the discharge from the ear followed an accident, I was led to believe that there was either a possible fracture with a spicule of bone pressing on one or the other of the canals, or a possible mass (bony) pressing or pinching the membranous labyrinth, or lastly, an erosion induced by the chronic suppuration, such an erosion would be increasing in depth or magnitude. Such a picture could easily be drawn when one remembers that the patient said that she had a discharge from her ear two or three times during the year preceding operation and that it would last but a few days.

From this reasoning I concluded that a radical mastoid operation would relieve her of this distressing vertigo. Cerebellar tumor had been excluded by Drs. Newmark, Lennon and myself, as the only other condition that would be likely to produce such symptoms.

Operative Findings.—No fracture of temporal bone (more detailed history, discharge from ear started before accident). Sclerosed mastoid, otherwise healthy macroscopically, with the single exception that the facial nerve was uncovered by caries anteriorly, and that at this particular place there was an erosion or excavation. This latter condition was found only after very careful search; at the time of operation, I did not think it sufficient to cause so much trouble. However, it proved to be correct and the day after operation the patient said her vertigo was less.

Neumann plastic, grafts. Uninterrupted recovery. Hearing before operation, whisper 3 feet; after operation, whisper 26 feet. Healing, twenty-four days. Vertigo and spontaneous nystagmus entirely gone.

Case 134.—*Patient.*—A school-boy, aged 17, had had a discharge from the ear for the last eight years. One year ago had pain deep in ear; no headache or vertigo.

Examination.—No pain on deep pressure or percussion. Complete destruction of drum membrane; foul, offensive discharge. Whisper, 6 inches. Weber to good ear. Rinné, negative. Schwabach, normal. C^1, positive. C, negative. c^4, positive. Watch on bone, negative. Tinnitus, positive. Vertigo, negative. Slight spontaneous nystagmus. Caloric reaction, positive (hypersensitive). Fistula symptom, negative. Seven-foot hearing-tube, positive.

Operative Findings.—Caries of the attic and antrum. Neumann plastic, graft, closed.

Hearing before operation, 6 inches. After operation, 6 feet. Duration of after treatment, twenty-four days.

Case 135.—*Patient.*—A school-boy, aged 9, had had a discharging ear for several years past; never had pain back of ear or deep in ear.

Examination.—Painful over the tip of mastoid, granulation tissue filling meatus, foul, offensive discharge. Whisper, 1 inch. Weber to opposite ear. Rinné, negative. C^1, positive. C, positive. c^4, positive. Watch on bone negative. Vertigo and tinnitus, negative. Spontaneous nystagmus, positive. Caloric reaction, positive (hypersensitive). Fistula symptom, negative. Hearing-tube whisper, positive.

Operative Findings.—Attic and antrum were full of granulation tissue, no mastoid cells. Neumann plastic, graft, closed.

Hearing before operation, whisper 1 inch, after operation, 4 feet. Twenty-eight days, cured.

The reason there is not more improvement in this case is easily understood when one examines the fork findings prior to operation.

Case 136.—*Patient.*—A girl, aged 7, had had a discharge from her ear "on and off" since 1 year old; six months previous to operation had an acute exacerbation, also considerable pain back of ear at that time.

Examination.—Whisper, 3 feet. Weber to bad ear. Rinné, negative. Schwabach, normal. C^1, positive. C, positive. c^4, positive. Watch on bone, positive. Vertigo and tinnitus, negative. Spontaneous nystagmus, negative. Caloric reaction, positive. Fistula symptom, positive. Hearing-tube, positive for whisper. Not painful on deep or superficial pressure; great amount of offensive discharge from ear; bulging of the posterosuperior wall, mass of granulations coming from above.

Operative Findings.—Pneumatic mastoid entirely destroyed by caries. Pyogenic membrane the size of a half dollar which pulsated when uncovered, looking very much like diseased dura. This cavity was almost as large as half an English walnut. The membrane must have been one-sixteenth or one-eighth of an inch in thickness and was more or less dense. The under part of the cavity was the dura mater which was covered by small granulations. The dura was uncovered until healthy dura made its appearance. Neumann plastic; grafts covering all but the diseased dura, closed.

Hearing before operation, whispering 3 feet, after operation, whisper 25 feet. Duration of after treatment twenty-eight days.

Case 137.—*Patient.*—A school-boy, aged 17, had had a discharge from ear for three years previously.

Examination.—No tenderness on percussion or pressure over mastoid. Entire destruction of tympanic membrane. Small polypi coming from above; partial destruction of bony attic wall. Whisper, 6 feet. Weber to diseased ear. Rinné, negative. Schwabach, normal. C^1, C, c^4, positive. Watch on bone, positive. Vertigo and tinnitus, negative. No spontaneous nystagmus. Caloric reaction, positive. Fistula symptom, negative.

Operative Findings.—Caries limited to the walls of the antrum. Dura covered by caries, the size of two thumb-nails, in the region of the attic. Neumann plastic, grafts over all, closed. Hearing before, whisper 6 feet, after, whisper 26 feet. Complete dermatization twenty-one days.

Case 138.—*Patient.*—A school-boy, aged 9, had had discharge from left ear since infancy.

Examination.—Not painful on deep pressure or percussion over the mastoid. Foul-smelling discharge; entire destruction of drum membrane. Whisper, 3 feet. Weber to non-suppurating ear. Schwabach, normal. C^1, C, c^4, positive. Watch on bone, positive. Vertigo and tinnitus, positive. Spontaneous nystagmus to opposite side and same side, more to opposite side. Caloric reaction, positive. Equilibrium disturbances negative. Fistula symptom, negative.

Operative Findings.—Caries extending to tip of mastoid. Neumann plastic, grafts, closed in usual way. Dressed in four days, every graft adherent.

More nystagmus to either side than he had before operation. *Did not speak of vertigo.* Left hospital in eight days.

ABSTRACT OF DISCUSSION

Dr. Hugo Frey, Vienna, Austria: The after-treatment of surgical operations is very important and any advance along that line must be welcome to us. Many do skin-grafting after the operation; very often, of course, not primarily but later on. In the clinic we have given up skin-grafting in these cases, because the results did not seem to be very satisfactory. Since I have been in this country I have seen a number of cases, especially in the hands of Dr. Welty, and I am induced to try skin-grafting again after the method advocated by him, because his cases have impressed me very much. Many of his patients show good hearing. It seems to me that the problem of the radical operation now is practically solved. But the question of the function after the radical operation has not been so well settled, as it seems to depend largely, not on the scars on the outer wall, but on the growth of the granulation tissue on the inner wall. Often we find considerable production of scar tissue in the inside as the result of operative work. It seems to me better to simplify matters by confining the healing process to the outer labyrinthine wall. The patients operated on in this way look better than when treated with simple plugging. It has been recommended to give up tamponading, but I must say the results then have not been so successful. The method of immediately tamponading the cavity with the patient's own tissue seems to be the method which will give the more favorable result and shorten the time, in comparison with the other methods. I find Dr. Welty did tamponading the first time only. It may be for this reason that the hearing function is so favorable after his operation.

Dr. H. B. Graham, San Francisco: My results in skin-grafting are about the same as those of Dr. Welty. The hearing in my patients is about the same as he has recorded. Alexander and Mackenzie, in Vienna, some two or three years ago made an examination of their patients in the polyclinic, as far as hearing was concerned. Whereas it was formerly thought there was a certain percentage of cases in which the hearing was made better by operation, they found that universally a year afterward the hearing was worse than before the operation. Dr. Welty has a good many cases in which he operated over a year ago, so that the lapse of time has evidently had no influence on the hearing in his patients, and he is to be congratulated on that point. Not only has the hearing been made better, but it has remained better. I think the after-treatment with the skin graft is just as long drawn out as the after-treatment in the other procedure. The patient is called healed in two or three weeks, but he has to be followed up for a long time after the operation. The tube is the responsible factor, I think, in a good deal of this delay in healing after a skin graft. Even after the healing of the cavity with epidermis, there is often still a discharge of pus, which comes from the tubal region. If the tube is washed out for two or three months the patient will eventually recover. But we must keep track of these patients for a month or possibly a year or even longer.

Dr. Henry Horn, San Francisco: The results of Dr. Welty are exceedingly interesting and the value of those results are just in proportion as they can be obtained by other men. The more witnesses the more convincing the conclusions appear. Dr. Graham has reported his cases. I have had, since I returned, only twelve cases of radical operation in which I could use skin-grafting and my results were uniformly good. The question arises, why are these results so good when men all over the world have tried skin-grafting only to give it up. Surgeons have already used petrolatum and oil and the application of pieces of cotton and various other methods somewhat similar to this have been applied in skin-grafting, but it seems that in this particular technic there is a fortunate combination and unless the operation is done exactly as described in the paper you will not get the same results. On looking into the wound after operation, it looks like an aseptic operation. The wound is practically healed when we take off the dressing. Of course, I do not agree with Dr. Graham at all when he says that the after-treatment is as difficult with the skin-grafting as it is otherwise. That is perfectly absurd. In fact, that is the most valuable part of this operation. One who has had to treat a nervous patient for a number of weeks by the older method can appreciate what a boon this technic is in the after-treatment.

There is one point yet to be solved, which would make this procedure an ideal one. In a few of my patients the entire cavity was practically healed at the first dressing. The exception is always in the region of the tube. In spite of most careful curettement with the Yankauer instruments, the closure of the tube is not always certain. I doubt very much if the grafts take in this cone-shaped cavity. On the other hand, I doubt very much if a graft could be spread across the cavity, thereby closing it off from the rest of the tympanum. My impression is that healing in this locality takes place by the filling in of granulations and the epidermization from the surrounding grafts. If this were not so and the technic was perfect, we should get a complete healing every time in about two weeks.

Dr. J. F. Barnhill, Indianapolis: I want to congratulate Dr. Welty on his results. They are certainly better than anything I have obtained. In regard to the hearing, granting that the grafts stick, I cannot understand why these patients should have better hearing than after natural epidermization. We know that after natural epidermization the patients do not hear so well as before the operation. Dr. Welty speaks of doing a smooth, clean operation and in that I agree with him, but it is often impossible to remove all of the disease. It is in my opinion unwise to guarantee this in any case. I have a specimen in which the cells go one-half inch deeper than the facial nerve and we know that the diseased cells often extend deep into the petrous portion of the temporal bone.

Dr. M. W. Fredrick, San Francisco: The brilliant results which Dr. Welty achieves have impressed me also, but I fear that, as in many other cases, their brilliancy will exceed their permanence. I object to the use of the word "cured" in this connection. I do not consider a patient cured until he can leave his physician and go wherever he chooses. Recently I have seen two or three patients operated on according to Dr. Welty's method, although they were not operated on by Dr. Welty. In all of these cases the resultant cavity was filled with a mass of débris and cholesteatomatous-like bodies that were removed with some difficulty. When a tissue that is foreign to the locality is used in repair one must expect these masses to form and to require attention several times a year. I prefer the somewhat more tedious process of allowing the cavity to obliterate itself, then the patient may be allowed to go at will.

Dr. Fred Stauffer, Salt Lake City: I would like to ask whether Dr. Welty selects his cases for this operation, and, if so, what kind of cases he selects. In our part of the country we have a great many cases of cholesteatoma, in which the dura and lateral sinus are often exposed, and in removing the diseased bone we often find that the facial nerve is exposed. In such cases the method Dr. Welty uses, of employing hydrogen peroxid and hot solutions, would cause paralysis of the facial nerve. It seems to me it would be difficult in some of these cases to make a skin-graft. I would like to know how he would treat such patients. I do not think his method would be applicable to all cases requiring operation.

Dr. E. C. Sewall, San Francisco: Before I heard Dr. Welty's communication before the San Francisco eye, ear, nose and throat surgeons some months ago, I had been using primary skin-grafts for a considerable length of time. At that meeting Dr. Welty made the statements he has made here, except that at that time he was doing his skin-grafting secondarily, and insisted that it should be done on the fourth day and never on the third or fifth. That evening I criticized his paper, because I felt that the readministration of an anesthetic is not desirable if it can be avoided. Since then Dr. Welty has adopted the primary skin-grafting. I have used the small pledgets which he recommends. He says that they should be counted and that is very necessary, but it is difficult to remove them by count, because they stick together and it is often difficult to know whether you have removed one, two or three of them. I have sometimes left some of those plugs and removed them later, to my chagrin. I found once after the third day a beginning facial paralysis. There was no paralysis immediately following the operation. It developed on the third day and was almost complete. On searching the cavity and removing some hidden pledgets, the paralysis gradually cleared up. There are certain objections to the applications of the grafts. I consider it absolutely unsurgical to do what Dr. Welty says, namely, to cover the exposed dura with skin-grafts. We all know that safety, after exposure of the dura, depends on the completeness of the exposure. If we make a puncture here we make a larger opening for safety. I am quite in sympathy with Dr. Barnhill's entire speech, in regard to facial paralysis, and more in sympathy with the point of view that there is danger in operating on a chronic suppurating middle ear. We will all get deaths if we operate often enough. The use of the cotton pledget is a difficulty. It is the best we have, but it seems to me it would be better if we had something else to use in applying the skin-grafts. I have even thought of something along the line of bismuth paste.

Dr. C. F. Welty, San Francisco: Of course, it is easy to find objections, but I have considered the various points brought up to-day and no doubt shall be able to answer the criticisms, if not in accordance with your notions, at least in accordance with my own. The only thing I have considered is the oiled dressing. In quite an extensive article Alexander and Mackenzie showed that all their patients have diminished hearing after one year. Now, the two series that I have shown here comprise thirty patients operated on in the last year, and in my report next year I expect to analyze the cases. I have patients who hear a whispered word 25 feet after more than a year. When I say that such results are better than anything before presented, you can readily understand my enthusiasm in this improved technic. The hearing is one of the important reasons that I present this particular improved technic. And the reason the hearing is good is that the cochlea is covered with a delicate epidermis. In the other process it is covered with cicatrical tissue from one-sixteenth to one-half inch thick. You can imagine what would result. In a series of thirty cases of this particular procedure the patients are all well. There have been relapses from the accumulation of débris, etc., and in that way pus may form and require care. A patient may require care once in a month, another once in two months and another once in a year. Much depends on the personality of the patient. In passing I will give you something that in my practice has worked very well. After clearing the ear of epidermis and débris, provided there is no pus, mop the cavity out with oil. I have seen patients treated that way, after six or eight months, without the formation of new epidermis. In regard to facial paralysis I have had now eight cases of facial paralysis prior to operation, one in an acute case and seven in chronic cases. Of those patients six recovered and the patient who did not recover was unconscious forty-eight hours before he was operated on and died. I have had no case of facial paralysis following an acute or radical ear operation, except a case of temporary facial paralysis due to pressure, which disappeared in ten days. The after-treatment is concise and precise. You must dry your cavity and you must do it in a delicate way and not put in the gauze in a reckless manner. You will possibly spend more time in the after-treatment than in the after-treatment of the other class of cases. But your time is well spent, for in a few weeks your patient is well. Dr. Sewall said occasionally your patients will die. But remember what I said: If the labyrinth is intact you can do pretty much as you please and the patients will not die.

THE RATIONAL TREATMENT OF FURUNCLES *

PENN G. SKILLERN, JR., M.D.
Assistant Surgeon, Out-Patients, University Hospital; Physician to Dispensary for Women, German Hospital.
PHILADELPHIA

While the treatment of furuncles seemingly may be summed up in two words—incision and drainage—yet I apprehend that a thorough, complete and permanent cure involves a broad survey of many principles, based on a brief consideration of their cause and pathology.

A furuncle, as described by Da Costa, is "an acute and circumscribed inflammation of the deep layer of the true skin and the subcutaneous tissue following bacterial infection of a hair-follicle or a sebaceous gland." The exciting cause is usually *Staphylococcus aureus.* Burrowing down into the hair-follicle and invading the adjacent sebaceous gland, the bacteria excite the surrounding subcutaneous tissue to inflammatory defensive reaction. The blood-vessels dilate and become engorged, resulting in active hyperemia. Leukocytes transmigrate and serum exudes into the zone of defense resulting in a little tumor which is hard, painful and tender. In the center of this little tumor, corresponding to the position of the hair-follicle, is a pinhead-sized vesicle containing clear or slightly turbid serum and projecting hair-shaft. The little tumor grows for three days until it becomes a relatively formidable looking object, harder, more painful and more tender. Regional lymph-nodes become acutely hypertrophied and equally hard, painful and tender. This unwelcome state of affairs causes the patient no little discomfort and a varying degree of septicemia brings on fever and malaise. On the fourth day, strangled by the great pressure of the acute tissue hyperplasia, the hair-follicle and sebaceous gland begin to ulcerate, and liquefaction necrosis sets in. The skin immediately around the hair is slowly dissolved. Liquefaction now proceeds more rapidly and the tumor, from being hard, becomes softened in its center, and fluctuation is palpated. The furuncle, while less hard, is still painful and tender. Left to itself the softened center projects more and more and on about the seventh day bursts, and seropus escapes, affording the patient some relief. Shortly a white slough composed of the destroyed hair-follicle and sebaceous gland and bacteria is loosened and expelled from the central cavity of the furuncle. It is followed by the escape of serum which soon becomes tinged with blood. There is now seen a little red pit exuding serum and blood and surrounded by granulations. The lymphadenitis subsides and the patient is comfortable. Granulations soon fill the pit and regeneration of epithelium completes the resolution of the furuncle.

---

* Read before the Philadelphia County Medical Society, May 24, 1911.

Predisposing causes are diabetes and other constitutional maladies, but more commonly violation of simple rules of hygiene. The established routine of "boils—look for sugar" is rarely fruitful. It will usually be found, however, that the patient is a little underweight, perhaps from overwork and insufficient or excessive or poorly selected food, and that he has become a little careless in the care of the surface of the body. He may be an athlete who thoughtlessly dons a suit soiled and sweaty from previous exercise, or a person who for sake of economy is equally careless about change of underclothing. He may wear frayed linen collars, whose edges grind bacteria-laden dust into the nape of the neck.

Prophylactic treatment, then, requires attention to nutrition and to hygiene of skin. Proper nutrition is maintained by sufficient plain, wholesome food taken at stated intervals and well masticated, and by daily evacuation of bowels to prevent absorption of intestinal toxins. A tonic of iron, quinin and strychnin, and free draughts of water, often from a quassia cup,. are desirable. Hygiene of entire skin requires antiseptic baths and fresh undergarments, preferably of linen mesh, daily. Local hygiene of nape of neck is important, and requires cropping of hair every fortnight, daily shampoo, and bathing with witch hazel or cologne water, and the wearing of clean, smooth and preferably soft collars. Scissors should be used on the nape of the neck instead of clippers.

The treatment of furuncles is divided into that of the furuncle itself and that of the low opsonic index of the blood. The immediate treatment of the furuncle itself varies according to whether it is in the stage of formation, the stage of ulceration and liquefaction necrosis, or the stage of resolution. When seen early in the stage of formation, the furuncle, if superficial, may often be decisively aborted in the following manner: Take a wooden applicator or matchstick and whittle to a fine point. Dip in liquefied phenol (carbolic acid). Shake off excess. Bore the point of this phenol-stick firmly and deeply into the vesicle in the center of the furuncle. Withdraw. In the wake of the stick there is seen a pit surrounded by a white eschar, aseptic because the active bacteria have been destroyed. A trace of blood may well up into the pit. The initial pain is quickly relieved by the anesthetic action of the liquefied phenol. If the furuncle is still in the early stage, but rather deep, a method recommended to me in a personal communication from Dr. George H. Simmons—that of injecting by the hypodermic syringe several drops of liquefied phenol right at the base of the furuncle—is effective. There is momentarily a sharp, excruciating pain, but after that, analgesia is established, and the patient freed from his previous tension-pain.

When seen late in the first stage it is common practice to make an incision. I believe this is wrong, for a furuncle, whether incised or not, completes its seven-day course as surely as night follows day. The furuncle still remains painful and hard. The incision in this case is futile because not in accord with the pathology of the lesion. A furuncle is a self-limiting process, always. The serum and leukocytes assemble to wage war against the bacteria. They seek to strangle and cast out the infected hair-follicle and sebaceous gland. This they eventually and invariably accomplish, on the principle of the sacrifice of one for the good of many. The knife, on the other hand, divides the infected hair-follicle and sebaceous gland and invades the demesne of those allies of health and foes of disease—serum and leukocytes. It shortens the process in no way, benefits the patient in no way, and leaves an entirely unnecessary scar. If healing takes place rapidly after incision, it is because the furuncle was well advanced, for in such case the slough will be found to be loose.

Given a furuncle late in the first stage, what is the most rational method of treatment? It would seem to be to establish an outlet, not for the beneficent serum and leukocytes, but for the products of liquefaction necrosis which are formed by Nature according to her best judgment, *secundum artem.* With the scalpel scratch off the little central vesicle. This causes no pain. A drop of discarded seropus follows and the ulcerating hair-follicle and sebaceous gland are exposed. Apply a Bier cup[1] and suck out as much as possible of the exhausted serum and blood. In the wake of the latter from nearby tissues comes fresh blood, with fresh serum and fresh, vigorous leukocytes. It is these that are going to cure the furuncle, and not the surgeon's knife. The knife inflicts unnecessary trauma, and gives the tissues two lesions to deal with instead of one. Often the vesicle does not even have to be scratched, in which case the cuticle is thin enough to be readily ruptured by the cup alone. Apply a dressing of plain sterile gauze wrung short of saturation from a solution of normal saline with sodium citrate. An important consideration in this method of treatment is that of drainage. If a gauze drain is inserted, it plays the rôle of a cork in a bottle. If left alone and allowed to dry, the lymph coagulates, thus plugging the furuncle. In keeping with modern pathologic conceptions what is desired is free bathing of the bacteria with fresh serum from the blood, with its highly antitrophic power. Sodium citrate, 1 per cent. solution, precipitates the calcium salts in the lymph and ensures a comparatively free outlet of the lymph discharge. By osmosis, the sodium chlorid sets up a flow of lymph through the walls of the furuncle, the citrate maintaining the fluidity of the serum. Thus, there is brought about a continuous flow of lymph of high antitrophic power from the congested blood-vessels through the wall of the furuncle and out through the wound. A bit of rubber dam may in addition be inserted if there is much tension on the outlet. The citrate is required for only about three days, and during its use the surrounding skin should be protected from pustulation by an ointment. The patient may make up his own solution for home use by adding a teaspoonful of sodium citrate and two and one-half teaspoonfuls of table salt to a glass of hot boiled water. Over this aseptic drain-poultice apply a piece of waxed paper or oiled silk, then a compress of non-absorbent cotton or wool and a cotton bandage. If the patient is going to lay up, leave the dressing open, instructing him to renew the drain-poultice frequently. The solution prevents the vesicle crusting over and the gauze absorbs the products of disintegration as Nature dispenses them. Sodium citrate should also be administered internally, 15 gr. three times daily after meals, both for its alkaline action on the blood, and for its diuretic action on the kidneys. The cupping and dressing may be repeated and renewed frequently

---

[1] While Sir Almroth Wright objects to the Bier cup on the same grounds that I object to squeezing, yet practically harmful traumatic effects are not apparent, and in any case are far overbalanced by the benefit that ensues.

(every four hours) until the slough is loose, when this may readily be removed by a pair of small dressing forceps. After this, no matter how the resolving furuncle is treated, resolution proceeds rapidly and uninterruptedly, and the resulting scar is always the smallest obtainable in proportion to the size of the furuncle. In most cases it is invisible.

In some cases the granulations, instead of being firm, red and rapidly growing, are flabby, bluish and sluggish. The trouble here I believe is due to relaxation of the tissues and mobility of the part. These conditions may be overcome by strapping the edges of the wound with adhesive strips which compress the granulations and immobilize the skin. Then the granulations are dried, mopped with tincture of iodin, and dusted with Bier's powdered nitrate of silver. Exuberant granulations should be snipped off with scissors; for, as Colles long ago pointed out in his lectures, the silver stick does not "burn down" granulations, as it is commonly supposed, but stimulates them. To promote epithelial regeneration—which, in this method, has a very limited area to cover—8 per cent. scarlet red ointment or amido-azotoluol may be employed.

I object to flaxseed poultices on the ground that, while they may soothe the patient, yet they devitalize the edge of the furuncle, prolong the period of resolution, and leave a legacy of an unsightly depressed scar. I object strongly to the bichlorid of mercury on the ground that it is a corrosive poison, that it devitalizes the vigorous leukocytes and disintegrates the beneficent serum; that it destroys feeble bacteria on the skin but does not reach the more active bacteria in the depths of the wound, and that on tender skin it causes pustules to spring up anew. I am unalterably opposed to incision for the reasons given above. If incise you will, then excise the furuncle entirely; otherwise withhold the knife.

How is auto-inoculation of adjacent hair-follicles to be prevented? By shaving the area of skin wide of the furuncle and disinfecting it with 70 per cent. alcohol, tincture of iodin with benzin, a dilution of liquor formaldehydi or of aluminum acetate. Local disinfection should be repeated at each dressing, benzin being an excellent medium thoroughly to cleanse the skin of wound discharges, effete products, and remnants of adhesive plaster.

Of course, if a patient presents himself for the first time with a furuncle well advanced in the second stage, where there is marked softening and fluctuation, in fact, merely a subcuticular abscess, a small incision through the thinned skin is indicated on the surgical principle of *ubi pus ibi evacuo.* This principle is in no way applicable to a furuncle in the first stage, because there is no pus to be evacuated. I strongly object to squeezing a furuncle in any stage. Squeezing is unsurgical in that it causes acute suffering quite needlessly, traumatizes the furuncle, breaking the barrier of protecting leukocytes, and provokes hemorrhage which interferes with drainage. Make the drain, aided by the Bier cup, remove the pus. It is less painful and at least equally efficient. To hasten the subsidence of the enlarged lymph-nodes and of the acute hyperplasia about the furuncle, thiosinamin may be given by mouth in 1½ gr. doses three times daily after meals.

Immunization against furuncles, when carefully and judiciously supervised, plays an important and efficient rôle. It is either passive or active. Passive immunization is indicated in the active stage of furunculosis, when a furuncle is present on the body, and consists in injecting antistaphylococcic serum, rich in antitoxins, near the infected area, twice a week. Active immunization is indicated in the passive or resting stage of furunculosis, to prevent subsequent appearance of furuncles. It is also efficient in the presence of a furuncle, the course of which is often considerably shortened. In bacteriemia, on the other hand, bacterins are contraindicated, because here they would add to the toxins with which the body is already surcharged. Bacterin therapy consists in injecting subcutaneously killed staphylococci —which act by virtue of their bacterins (bacterial toxins)—in ascending doses, the body cells thus producing more and more antitoxins until the opsonic index is restored to normal. With this accomplished, the patient is not only immune to staphylococcic invasion, but his serum, now rich in antitoxins, could be used passively to immunize another patient with active furunculosis, but the potency of such serum is difficult to determine.

Most efficient are the autogenous bacterins. These are prepared by identifying and isolating the organism from a furuncle, scraping loopfuls from an agar slant, suspending in saline solution and killing by heat. At the University Hospital we suspend approximately 400 million killed bacteria in 1 c.c. of saline. Starting with an initial dose of 0.25 c.c., we increase by weekly injections to 2.5 c.c., the size of the increasing doses depending on the degree of reaction as shown by headache, malaise and possibly fever. While control by clinical symptoms is usually sufficient, yet to perpetuate the cure the patient's opsonic index should be taken at weekly intervals, to anticipate a change from a positive to a negative stage. The waning of the attacks of furunculosis is often indicated by the appearance of abortive furuncles.

The next best treatment of recurrent furunculosis is by yeast (*Saccharomyces albicans*), which stimulates phagocytosis and liberates carbonic acid, thus recalling John Hunter's recommendation of carbonate of sodium for boils. While brewer's yeast (*Oberhefe*) is inelegant pharmaceutically, is a nauseating substance and is hard to keep and to handle, yet it has strong advocates. I have seen furunculosis checked by the use of nuclein in the assimilable form of compressed tablets.

This method of treatment, then, commends itself because it is gentle, simple, painless, rational and effectual. Where, as sometimes happens, the furuncle is exceptionally large and severe—the carbuncular furuncle of some writers—I employ a little operation which seems to meet the indications very well. I fill a hypodermic syringe with a 3 per cent. solution of novocain, enter the needle through the sound tissue at the margin of the furuncle and plunge it under the base of the tumor. After waiting five minutes until the furuncle is completely anesthetized, I take a small curet and remove the core from the center of the tumor. This method is also applicable to furuncles on the face where, because of the wide-spread infiltration from the laxity of the tissues, there is danger of sinus thrombosis by way of the facial and ophthalmic veins. In case the supposed furuncle develops into a full-fledged carbuncle—and it is often impossible to say whether we will have to deal with a furuncle or a carbuncle except with the lapse of time—the safest and surest treatment is excision of the entire carbuncular area, hemorrhage being controlled by the Paquelin cautery and firm compresses, and pure liquefied phenol being applied. Thus will the progress of septicemia and of its effect, cloudy swelling—particularly of the kidneys—be checked, and often the life of the patient saved.

THE NATURE OF THE VIRUS OF MEASLES *

JOSEPH GOLDBERGER, M.D.
AND
JOHN F. ANDERSON, M.D.
Respectively, Passed Assistant Surgeon, and Director of the Hygienic Laboratory
WASHINGTON, D. C.

As soon as we had satisfied ourselves of the susceptibility of the monkey to inoculation with measles[1] we turned our attention to the study of the nature of the virus as it exists in the circulating blood. Accordingly we made experiments to determine its filterability, its resistance to drying, heat, freezing and "age," and now desire to present briefly some of our results, reserving greater detail for publication in a bulletin that will cover all of our work.

FILTERABILITY

We have made four separate attempts to determine this point. In each case the blood-serum was obtained by centrifugation of defibrinated blood and was diluted with three volumes of saline solution before filtering through a Berkefeld candle.

Our first two experiments appeared to be negative. In our third experiment we inoculated four monkeys with filtered serum which on account of an accident we had been obliged to pass through two Berkefeld candles. Of these four animals only one, Rhesus 101 b, presented any recognizable evidence of a reaction.

In our fourth experiment, following the inoculation of two Rhesus monkeys (113 a and 113 b) with filtered serum, one, 113 a, developed a well marked reaction with an eruption which began to appear twenty-one days after inoculation. From this animal we obtained some blood with which we inoculated two others, one of which, (a *Macacus sinicus*) No. 125, later developed a fairly well defined febrile reaction.

We conclude from the foregoing that the virus in measles blood is capable of passing through a Berkefeld filter.

DRYING

We have two experiments to record. In each the required amount of defibrinated monkey blood was put into a Petri dish and this with its cover tilted placed over concentrated sulphuric acid in a desiccator. The air was quickly exhausted from this apparatus and it was then placed in our cold room at 15 degrees C. At the end of twenty-four hours under these conditions the blood was found as a dry scale. This was rubbed up and dissolved in saline solution and then used for inoculation.

In our first experiment we inoculated two Rhesus monkeys, Nos. 107 a and 107 b. Of these animals No. 107 b gave no recognizable evidence of a reaction while No. 107 a presented, ten days after inoculation, only a slight rise of temperature that was sustained for two days. Subsequent reinoculation of both animals with virulent blood was followed in neither by any appreciable indication of a reaction.

In our second experiment we used the defibrinated blood of Rhesus No. 110 a, and, as in our first, after drying inoculated two Rhesus monkeys, Nos. 116 a and 116 b. Following this inoculation No. 116 b presented a well marked reaction with an eruption which began to appear fifteen days after the inoculation.

We conclude that the virus in the circulating blood of measles may resist desiccation for twenty-four hours under the conditions of the experiment.

HEAT

We have made three attempts to determine whether the virus in measles blood retains its infectivity after heating, in one experiment at 57 C. and in two at 55 C, for fifteen minutes. None of the monkeys inoculated with blood so heated has given any recognizable evidence of a reaction although the unheated blood used in each case was shown to be infective by control inoculations.

This, we think, strongly indicates that the virus of measles does not retain its infectivity when heated to 55 degrees for fifteen minutes.

FREEZING

We froze some defibrinated blood from Rhesus 110 a shown by controls to be highly infective, by putting a test tube containing it into a freezing mixture, the temperature of which was a little under 13 C. It was kept frozen solid at a temperature between 13 C. and 0.0 C. for twenty-five hours. At the end of this time the blood was quickly thawed out, warmed to 37 degrees and inoculated intravenously in a Rhesus monkey (No. 118 a). Following this inoculation the animal developed a reaction marked by the appearance of an eruption that was first noted twenty-six days after the inoculation.

The virus appears, therefore, to have resisted "freezing" for twenty-five hours although the long incubation period would perhaps indicate some reduction in its virulence.

We think it right to add that some doubt of the validity of this experiment exists because the animal was inadvertently exposed to "contact" during the period of observation. While we are unable to exclude the possibility of contact infection our experience inclines us to believe this possibility rather remote in this instance.

AGE

We made two experiments to test the "keeping" quality of the virus in measles blood. Virulent defibrinated monkey blood was kept in a sterile test-tube plugged with cotton, at 15 C. for twenty-four hours in the first and for twenty-five and one-half hours in the second experiment. At the end of these periods the blood was used for the inoculation of monkeys. Neither of the two inoculated in our first experiment presented any recognizable evidence of a reaction.

Of the two animals inoculated in our second experiment only one (No. 117 b) gave any suggestive indications of a reaction. In studying the temperature curve of this animal one notes a moderate rise on the fifteenth day after inoculation followed by a decline, and this by a second rise of equal degree sustained for about six days.

We are inclined to interpret this as a reaction, and, therefore, think it probable that the virus still retains some of its infectivity after twenty-four hours at 15 C.

SUMMARY

We may summarize our conclusions as follows: The virus in measles blood may (1) pass through a Berkefield filter, (2) resist desiccation for twenty-five and one-half hours, (3) lose its infectivity after fifteen minutes at 55 C, (4) resist "freezing" for twenty-five hours, (5) possibly retain some infectivity after twenty-four hours at 15 C.

It is a pleasure to express our indebtedness to Dr. H. B. Deal, attending physician and Dr. A. C. Smith, resident physician, Garfield Hospital, to Dr. H. A. Fowler and to Dr. J. R. Wilder for access to cases of measles. We are also grateful to the medical profession of the District, particularly to Drs. Percy Hickling, R. T. Holden, E. E. Richardson and M. O. Dumas for their courteous cooperation in offering us access to some of their measles patients.

PREVENTIVE MEDICINE SECTION COMMITTEE REPORTS *

REPORT OF COMMITTEE ON STATE METHODS OF PUBLIC EDUCATION IN HYGIENE †

I. SHOULD STATE BOARDS OF HEALTH UNDERTAKE AN EDUCATIONAL CAMPAIGN IN HYGIENE?

There seems to be not a shred of an argument against the opening and the continuing of a strong campaign of education of the public in hygiene by state, city and town boards of health. The advantages would be many and the disadvantages none. That the public sadly needs the education, appears in the fact that not 2 per cent. of all people born escape being stricken with preventable ailments. The masses of people do not know how to breathe, do not know why they breathe and do not know what they breathe. Dust, smoke, the products of combustion and vile odors, so far as their hygienic bearing is concerned, are simply words to them. The masses are beginning to have permanent glimmerings of the importance to health of drinking pure water and pure milk, but are not yet quite ready to stand the expense by which these blessings are to be obtained.

The necessity of hygienic housing for the benefit of society and the nation by raising the general health is yet little appreciated by those who are directly affected, is not at all appreciated by those who own living blocks, and business men generally are all too indifferent. Well-to-do farmers and well-to-do merchants, in not small numbers, still strongly oppose the erection of sanitary school houses on account of the initial expense; they oppose necessary sewers, they oppose building good roads and streets, they oppose drainage for the purpose of conquering malaria, and they settle any proposition to conform to the laws of health, by hurling the epithet "crank" at any one having the temerity to propose such a thing. Yes, public education in hygiene is badly needed, and the labor properly falls on health authorities.

II. WHAT SHOULD BE THE FINANCIAL PROVISION FOR SUCH A CAMPAIGN?

The answer to this depends on many conditions. If hygiene be effectually taught in the public schools and if medical inspection of school children is in force, then, within a decade, public health exhibits and pamphlet distribution may largely be done away with. Until then, however, public exhibits, pamphlets, bulletins and lectures are decidedly in order. The expense must, with rare exceptions, be borne from public treasuries, and a vital question is, how may the said treasuries be opened for this good purpose? In instances, funds may be secured from persons who are the holders of accumulated wealth; and such source might appropriately be termed accidental. Wherever it can be laid hold on, there most probably will be found a practical philanthropist who will be keen enough to do it.

In order to secure funds for such work from public treasuries, certain influential members of the laity must be converted to the cause, and they must publicly express themselves. In the state of Indiana, Governor Thomas R. Marshall was convinced by his own family physician and other members of the profession of medicine that in preventive medicine the state would find a source of revenue, a source of strength, and a source of happiness. He spoke forth his convictions from the platform and in message and the holders of the keys to the money-boxes listened and heeded. In consequence, eight out of nine bills bearing on different phases of preventive medicine were enacted into law and the appropriation of the state board of health was doubled. The lesson is, those interested must make politics out of humanitarian and philanthropic causes, showing their economics, in order to secure the wealth and happiness to society which lie in such forces.

As to the amount of money necessary to carry on campaigns of education in public health work, this will depend on many conditions, but it may be safely predicted that the practical politicians, holding the strings to the public money bags, will not loosen said strings sufficiently to swamp the cause.

III. SCHEMES OF ORGANIZATION

1. Each state board of health and each board of health of large cities should have a bureau of education, or a publicity bureau with a superintendent whose whole time should be given to this phase of public hygiene. Said superintendent should, of course, be capable; but more, his heart should be in his work and he should stand ready at any time to make large sacrifices for the cause.

2. Proper help, in numbers and character, in the line of intelligent clerks should be provided, and every effort put forth to secure the moral support of the people.

3. Proper pecuniary support must be secured. Obviously the amount must be commensurate with the work that is projected and if not, the process must be reversed, and the work projected must be commensurate with the appropriation.

4. A scheme of organization for a department of publicity must be according to the size of the state or city and the moneys available, and no syllabus for said organization will be offered herewith.

IV. METHODS OF MAKING USE OF EXHIBITS AND LECTURES

Of course a Cæsar or a Napoleon would make use of and find advantages in general methods of any kind and for any purpose which would be unthought of by the ordinary person, and so, whatever force or advantage any one method of addressing the public might have will depend on the man in command.

Car Exhibits.—The excellent examples set by Louisiana and California in the matter of traveling exhibits could well be followed by other states. The financing and the securing of the aid and cooperation of the railroads are the first two steps in the enterprise. These being secured, the character and arrangement of the exhibit follows. The aid of the press, on account of its unusual comprehension of public needs, is always easily secured, and said aid may always be assured to be at hand.

The coming of an exhibition car to a community should be fully heralded in the local press; posters, descriptive and explanatory of the exhibit, should invariably precede the car, and it would be well to have a box for contributions in a conspicuous place and to supply tags for all visitors. These would lend a personal interest to visitors and especially to contributors.

Hall Exhibits.—While car exhibits have the advantages of novelty, rapid transportation and always being in order, still, they must be expensive and the space is not large. Halls for hall exhibits may quite always be secured without rent, even an empty store room answering the purpose very well. Indeed, such rooms are to be frequently preferred because they are usually in the business district of a town and very accessible. It is certainly true of the car and the hall exhibit; both have their advantages and both should be used.

Lectures and Sermons.—Illustrated and not illustrated, lectures and sermons are usual and excellent methods of educating the public. The effectiveness of speakers will differ greatly, but sincere, earnest and plain presentation of the facts will always be potent in arousing action. Unless action is aroused, the lesson is of little worth. The presentation of moving pictures will not be forgotten, although the very refined police of Indianapolis did forbid the showing of the now famous fly film, which has done such excellent service in cities and towns everywhere in the land. In Indianapolis, a woman complained to the police that the maggots hatching into flies shown by the fly film made her sick, and the horrid thing should not be exhibited. The police responded and suppressed the show and it was afterward found that the maggot-passing-into-fly process was actually and really happening in the complaining woman's backyard and also in many places near the police headquarters. The incident is related simply to show that certain kinds of women and certain kinds of police must be considered in getting up exhibits for the instruction of the people in any of God's truths.

† Other reports will appear in succeeding issues

V. HEALTH OFFICERS' SCHOOLS

Schools for health officers are a real necessity in these days. Health officers should be called together at least annually by state boards of health or health commissioners, that matters pertaining to public hygiene may be discussed and acted on, that instruction might be given by persons who have become prominent in the work, and also that all may profit by criticisms and through questions and answers. The enthusiasm and interest which health officers' schools arouse in an invaluable help in the cause.

Public Schools.—The most promising soil in which to plant the seeds of hygiene is the public schools. The minds of children, being plastic and receptive, will readily accept and assimilate new truths, and these becoming a part of the composition of the child will find practical expression when adult age is reached. It sometimes seems to be a waste of time to try to secure the action of adults in the matter of the practical application of well-known hygienic truths. They, in considering the matter, remember they have survived, and then draw wholesale conclusions to the effect that the truths and arguments presented in regard to disease prevention are all bosh.

The advice given by President David Starr Jordan is certainly sound: "If ever you wish to go in for philanthropy, if ever you wish to be of any use in the world, do something for little children." And further, "If the great army of philanthropists ever exterminate sin and pestilence, ever work out our race's salvation, it will be because a little child has led them."

Posters, Wall Cards, Etc.—The usefulness of posters, wall cards, charts, cartoons, pictures, etc., in education is very great. Directions for preparing them cannot be given, as they must be devised by the intelligence, tact and ingenuity of the individual. The posters and charts presented by the New York Health Commissioner and other health authorities are most ingenuous and excellent. They all forcibly illustrate various phases of disease prevention, and health authorities who find themselves unable to excel such charts and posters will undoubtedly be given permission to use those from other states on request.

Bulletins.—All kinds of bulletins in all kinds of causes have always been effective. A fully successful bulletin treating any phase of the public health cause will depend for its success on lucid and striking expression. The prosy, dull bulletin, telling its story in humdrum style, will never make a hit. It will not interest and will not cause its readers to act. The healthgrams of the Chicago Health Department Bulletin, and like grams of other bulletins, have made good and lasting impressions. The lesson is that bulletins on health subjects must be bright and original, presenting their matter briefly and strikingly.

The Press.—Most potent of all educational forces, except the schools, is the press. We are a nation of newspaper readers and through the papers is found the best method for immediately reaching the public. Everywhere newspapers most gladly publish live readable matter on public hygiene. Without the aid of the press public health work would move slowly indeed. In using the press, as in other methods of reaching the public, success depends very largely, perhaps altogether, on the tact and talent of those who prepare the matter.

J. N. HURTY, Chairman, Indianapolis.
WILLIAM F. SNOW, Sacramento, Cal.
OSCAR DOWLING, Shreveport, La.

ABSTRACT OF DISCUSSION

DR. W. F. SNOW, Sacramento, Cal.: The subject of educating the public should be divided into at least two divisions: the children and the "grown-ups." At the age of 14, 85 per cent. of children leave our schools never to return. The problem, therefore, is very different with our children up to the age of 14, and from that age on.

In the teaching of children I believe the most important new factor for us to emphasize is the use of the moving pictures. Somehow or other, teachers are very slow to utilize this wonderful mechanical invention. Our high schools are nearly all equipped with stereopticons, and many of our grammar schools are similarly equipped and have weekly lantern-slide shows; but the moving picture itself, which is the same kind of a mechanical device, is not used, and many teachers think that moving pictures are to be frowned down. In California we are trying to have arrangements made for a weekly educational day in every town which has a moving picture show.

We have had some experience in California with a traveling sanitation car, which I think was the first one sent out in this country. We had to operate some such plan to cover the great distances in California. This car has had a great influence with the schools, but as Dr. Hurty has emphasized, these methods are somewhat transitory. They create a great deal of interest at the time and do excellent work in getting newspaper publicity, in distributing literature and in reaching all the children of the schools with preliminary impressions of public health and hygiene. But permanent results do not follow unless such general methods are supplemented with something else that is more durable.

Just now in California we are trying a supplementary experiment with what we call small serial demonstrations. We have small relief maps, so provided with models of houses, dairies, vegetable gardens, etc., that the children may lay out the sanitary situation in their own districts and then move these houses around to correct the bad features. In other words, the outfit is designed to teach the children at the round-table to play sanitary games. These outfits are boxed up, sent out to the different schools for a period of a week or two and then sent on to other teachers. In a similar way we are sending out small bacteriologic exhibits. We have a pure food exhibit along the same lines. The State Board of Health is sending these out in an effort to stimulate communities to establish permanent work along these lines in their schools.

So far as general results are concerned, Dr. Hurty has undoubtedly wisely emphasized the newspapers. If we stop to think of it, when we lose 85 per cent. of our children at the age of 14 or 15 from our schools and they go into our industrial occupations, from that time on they never get any organized instruction except through the daily and weekly papers of their community. I believe that the newspaper is truly the great educational system for adults at the present time. We have only just begun to realize this, and to cooperate tactfully and efficiently with the newspaper editor in utilizing his opportunity in the field of education.

In regard to exhibits, up to the present we have largely gone before the public without any attempt at correlating the ideas put forward. The result is that the public believes all these things to be a matter of hobbies. We must work out some scheme for presenting to the public all the time a connected, comprehensive idea of health conservation in all its phases, no matter what particular phase is being agitated in the community at any given time.

DR. FRANCES M. GREENE, Cambridge, Mass.: Until now sex-education has always been relegated to the mother; seldom to the father or the physician; and the physician has always lent himself to the little fairy tale which forms the first lie that a child is obliged to hear. But when the great congresses met in order to face the question and to solve the problem of venereal disease, they all turned to the mother and said, If we want to do *anything* to help these conditions, we must begin by teaching the infant, by being serious with the child. This was very easy to say, but exceedingly difficult to do;

and I find, after several years of work in trying to teach mothers how to be sincere, that we need help in all directions; and in this the doctor can serve us greatly. The family physician should do his best to make the mother realize, not only what she is going through at childbirth, but the responsibilities she is going to take on herself; and that what is about to happen to her is one of Nature's mightiest phenomena, whose significance should be reverently understood by the children in the household. She should not try to conceal her position, and nothing can help so much as having the family physician talk to the father and make him realize his responsibility in the matter.

In the first place, the first question that the child asks should be answered with sincerity instead of falsehood, coldness and very often a distinct rebuff. Then the confidence between the parent and the child will be made fast; the child will not turn elsewhere for information which the parent can give best of any one; and as he grows to puberty, instead of getting information about the most necessary and natural things from strangers, the mother and father will be his natural teachers. Then by a very easy and natural process, when the boys and the girls go out into the world, they will be told about the dangers which they are there to meet, and be prepared to meet them. In this matter the physician can greatly help or greatly harm. I have had women say to me: "What can I do when I go to my physician and tell him that my boy has had night emissions, and he answers that the only cure is to send him to a prostitute?" or when the boy is given a latch-key and sent by his own father as soon as he is 14 or 15?

Dr. William C. Woodward, Washington, D. C.: A method of educating the people that has not been referred to at this meeting was forcibly pointed out at the general meeting this morning, in a letter that was sent to the Association by Senator Robert L. Owen. In substance, he pointed out that if we would have the people believe our teachings and live up to the principles that we enunciate, we ourselves must follow such teachings and live up to such principles. And what is true of individuals is true also of communities. No city or state, nor the federal government itself, should impose on the individual sanitary requirements which the city, or the state, or the federal government does not live up to.

Dr. Oscar Dowling, Shreveport, La.: In Louisiana, since Nov. 5, 1910, we have made a state-wide health-educational campaign. The majority of the people, not only in Louisiana, but in many other states, do not know how to practice the simplest health rules, or know why they are necessary. They think of disease as inevitable. This is no reflection on them. It means simply that we, as a nation, have not emphasized principles of hygiene and sanitation either in legislation or administration. I believe Louisiana has the distinction of being the only state in the Union to own a health train. In our campaign these cars—two containing exhibits, one used as living quarters—were transported over 7,000 miles in the state. Two hundred and fifty-six towns were visited. Nearly three thousand inspections were made. In order to have accurate personal knowledge of conditions and a correct judgment of the attitude of the public mind toward health reform, I myself made these inspections, with very few exceptions.

It has been estimated that eight years could be added to the normal period of human life by merely securing reasonably pure air, water and milk. Having this in mind and the tremendous importance of food in physical welfare, the effort was to make plain to all those engaged in manufacture, production, or sale of foodstuffs, that surroundings, including the method of handling, must come up to a certain standard of cleanliness. Dairies especially were selected as an object lesson. Five hundred and eighty-one were inspected. I am sorry to say conditions in some were rather bad. In one town our officers picked up one morning six samples of milk. Five of the six had been watered. One dealer on being asked to show cause why he should not be prosecuted replied that he had brought it 3½ miles. If he didn't add water, the milk was so rich it would turn to butter before he could get to town. The score card of the American Dairymen's Association was adopted and we require that every dairy to receive a permit to sell, shall score 50 points. We taught the people how the actual cleaning should be done. We require a tuberculin test and when the cows react, they must be slaughtered. We find that in the country where the herds are kept in the open, fewer react. In one herd of 180 in the city, 37 reacted; in the country in four herds numbering 300 there was only 1. Since the inspection tour many dairies have been remodeled, and we believe the time is near when Louisiana will have as pure a milk-supply as any other state in the Union. Nearly every slaughter-house inspected was condemned. These are being replaced by sanitary and modern structures. In this campaign instruction in prevention of disease was given in every talk, demonstration and lecture. Louisiana, as all members of the medical profession know, is free from yellow fever. Now we want to get rid of the mosquito. Cleanliness and drainage will do this and as a result we shall be practically free from malaria.

It was predicted that the abolition of the public drinking cup would meet with much opposition, but we had four months in which to carry on this educational campaign before the regulation went into effect and we are glad to say that the people are loud in their praise of its abolition. The enforcement of this law has had a widespread educational influence. In effect it enters into the lives of many classes of people.

We have secured beyond our hopes the cooperation of the citizens in the reporting of births and deaths. A little story of Dr. Hurty's relative to a lost inheritance seemed to appeal to the people and arouse their interest. A regulation which will go into effect July 1 will further protect the people from infectious disease, namely, the abolition of the common towel. Foodstuffs also, after July 1, will be further protected by the regulation which requires wrapping of bread and protection of other products from dust and flies. We have the cooperation of the people throughout the state and believe that Louisiana, in response to an earnest effort for ideal conditions, will be in a short time as clean—we won't say cleaner—but we hope will be just as clean as any other state in the Union.

REPORT OF COMMITTEE ON STANDARD METHODS OF PROCEDURE FOR THE CONTROL OF BOVINE TUBERCULOSIS IN RELATION TO MILK-SUPPLIES*

We, the committee to whom was referred the question concerning standard methods of procedure for the control of bovine tuberculosis in relation to the milk-supply, beg leave to suggest the following recommendations as a basis for laws, regulations and ordinances by municipal health officers:

1. That all cows on dairy farms producing milk for market purposes be tagged, tattooed or otherwise marked for identification.

2. That (a) all milk produced on such dairy farms shall either come from tuberculin-tested cattle, which shall be retested at least once a year; or
   (b) if sold from untested cows the latter must be given a careful physical examination every three months by competent veterinarians accepted by the board of health, all suspicious animals being eliminated, and the physical score-card of each animal in the herd filed with the proper health authorities (commissioner, board, veterinarian); or
   (c) the milk must be subjected to pasteurization under the supervision of the health authorities in case the herd is not handled in accordance with the above requirements.

3. That no additions to any herd, whether the herd has been tested or not, shall be made in the future without subjecting the additional cattle to the tuberculin test.

4. That no license for the sale of milk shall in future be granted except to applicants having herds known to be free from tuberculosis, as indicated by the tuberculin test.

5. That the [illegible] any udder affection, or anthrax, rabi[illegible] conditions, or clinical symptoms of [illegible] utilized as human food,

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

even though the milk be pasteurized. Milk from cows fifteen days before and five days after parturition, and that from animals receiving any deleterious medicaments or foodstuffs shall likewise be excluded.

6. That veterinary inspectors of health departments make frequent visits to dairies having untested herds, in order that they may discover all advanced cases of tuberculosis, or udder tuberculosis, as early as possible.

We favor the amendment of all state laws in order to make them include the following features:

1. The compulsory testing of all dairy cattle and the requirement of certification of the tuberculin test for all dairy cattle sold, except for purposes of immediate slaughter.

2. The adoption of an official system of marking reacting animals in such a way that they can be definitely identified.

3. The payment of appropriately-guarded indemnity to all owners of tuberculous cattle which come under the respective jurisdictions of the various states, the said animals to be slaughtered in abattoirs having federal, state or other efficient inspection. Exceptions should be made in case of cattle valuable for breeding purposes, but such animals must be kept in quarantine under strict supervision.

4. The prohibition of the sale or feeding of unpasteurized milk from reacting cattle.

THE TUBERCULIN TEST

1. "That tuberculin, properly used, is an accurate and reliable diagnostic agent for the detection of active tuberculosis.

2. "That tuberculin may not produce a reaction under the following conditions:

"(a) When the disease is in a period of incubation.
"(b) When the progress of the disease is arrested.
"(c) When the disease is extensively generalized."

"The last condition is relatively rare and may usually be detected by physical examination.

3. "On account of the period of incubation and the fact that arrested cases may sooner or later become active, all exposed animals should be retested at intervals of six months to one year.

4. "That the tuberculin test should not be applied to any animal having a temperature higher than normal.

5. "That any animal having given one distinct reaction to tuberculin should thereafter be regarded as tuberculous.

6. "That the subcutaneous injection of tuberculin is the only method of using tuberculin for the detection of tuberculosis in cattle which can be recommended at the present time.

7. "That tuberculin has no injurious effect on healthy cattle.

"That a positive reaction to tuberculin in any properly conducted test, official or otherwise, in any animal in any herd, shall be considered evidence sufficient on which to declare the herd to be infected." (From report of International Commission on the Control of Bovine Tuberculosis.)

In the application of the tuberculin test as well as in the interpretation of the results obtained, the following conditions are recommended in order to secure uniformity of procedure:

1. Keep stable cattle under usual conditions and among usual surroundings, feeding and watering in the customary manner.

2. Make a physical examination of each animal, and give to each one some designation by which the animal will be known throughout the test.

3. Take each animal's temperature at least three times at two- or three-hour intervals on the day of injection; for instance, at 2, 5 and 8 p. m. When the last preliminary temperature (which would immediately precede the injection) registers above 103 F., the injection of the tuberculin should not be made; the test of such animal should be postponed.

4. At 10 p. m., inject a dose of tuberculin under the skin in the region of the shoulder, using a sterile hypodermic syringe, after disinfecting the skin at the seat of injection with a 5 per cent. solution of carbolic acid or a similar antiseptic solution.

5. The dose of tuberculin (Koch's original concentrated) is from 0.25 to 0.33 c.c. for adult animals, weighing about 750 pounds. It is convenient to dilute this with a 0.5 per cent. solution of phenol (carbolic acid) until the size of the dose to be given is 2 c.c. Yearlings and 2-year-olds, according to size, should receive from 1 to 1.5 c.c. of such solution, while bulls and very large animals may receive 3 c.c. Double, or even triple, doses should be given to cattle recently injected with tuberculin; also in the case of animals which, on physical examination, are supected of being tuberculous.

6. At 6 a. m., on the day following the injection of tuberculin commence taking temperatures, and continue every two hours until the twentieth hour after injection, at which time if there is no tendency for the temperature to rise the test may cease.

7. A rise of 2 F. or more above the maximum temperature observed on the previous day, or one which goes above 103.8 F. should be regarded as an indication of tuberculosis, provided the temperature reaction shows the characteristic rainbow curve.

8. Animals which, after injection, show a rise in temperature of 2 F., with a maximum between 103 and 103.8 F., as well as those which show a rise less than 2 F., with a maximum temperature of 103.8 F. or more, are to be regarded as suspicious. These suspicious cases should be held for a retest six weeks later, giving double the original dose.

9. The ophthalmic, cutaneous or intradermal applications of tuberculin are still in the experimental stage, and cannot be recommended for a routine practice at the present time.

Bureau of Animal Industry, Department of Agriculture, Washington, D. C.

REPORT OF COMMITTEE ON REGULATIONS FOR THE PASTEURIZATION OF MILK*

1. No milk shall be used for pasteurization which comes from a dairy scoring less than 55 on the Department of Agriculture score-card, which has been scored by an official inspector.

2. The milk must have been kept cool (below 50 F.) from the time it leaves the dairy to the time it reaches the pasteurization plant and shall be kept below 50 F. at the plant up to the actual time of pasteurization.

3. The "flash process" for pasteurization is to be condemned.

4. The "holding process" shall be the only process recognized as efficient. The milk must be held for twenty minutes at 145 F., or for five minutes at 160 F.

5. The heated milk must be cooled immediately after the period of holding has elapsed to 50 F. or below.

6. Automatic temperature devices recording the exact temperature in the pasteurizing machine during the process are to be attached, and keys for these devices are to be kept by the health department.

7. Bacterial counts and acid determinations to control efficient cooling during transportation shall be made at regular intervals. These counts should be made before and after pasteurization to control the efficiency of the pasteurizing process.

8. Pasteurized milk, on leaving the pasteurizing machine, should not contain more than 50,000 bacteria per cubic centimeter, no matter what the initial bacterial content of the raw product was.

9. The pasteurized milk must be kept below 50 F. up to the time of delivery to the consumer.

10. Pasteurized milk should be designated as such on the bottle cap or in any other suitable manner.

11. Employees in the pasteurization plant should be subject to medical examination at regular intervals. If any employee contracts a contagious disease, this fact should be reported to the health department without delay.

12. Pasteurized milk should receive the same care as raw milk under all conditions.

Committee.

ABSTRACT OF DISCUSSION

DR. L. M. POWERS, Los Angeles: The proposal is a very good one. I would like to make one amendment. Milk should not be allowed to be pasteurized more than one time. It is not a provision of our ordinance at the present time; but I see that we will have to enact it. Milk that is shipped from a long distance into the city is pasteurized more than once: pasteurized up north, a couple of hundred miles from here;

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

shipped in here and then, to prevent it from spoiling, is repasteurized; if the delivery wagon goes out and any milk has been returned undelivered, again it is repasteurized. If it is not spoiled the customer gets it after three pasteurizations, or three cookings. Otherwise, I think the provisions are excellent.

Dr. William C. Woodward, Washington, D. C.: In determining whether milk is or is not fit for pasteurization, it is not, I believe, possible to rely absolutely on the mere rating of the dairy farm in terms of the total score attained as shown by the score card of the Department of Agriculture or by any other score card. The Department of Agriculture allows on its latest score card for conditions pertaining directly to the cattle themselves fourteen points out of a possible 100. It would be quite possible, therefore, to have every cow in the herd tuberculous and dirty, and yet to have the total score for the dairy farm above that fixed by the committee as entitling the milk to use for pasteurization. In order to determine the meaning of a score card, it must be interpreted by some one trained for that very work. The total score considered alone means very little, and no rule of thumb can be adopted for determining the significance even of the detailed score.

REPORT OF COMMITTEE ON THROAT CULTURES*

Your committee, after having conducted an investigation of the present status of methods of throat culturing for the diagnosis of diphtheria, has elected to submit the accompanying report of progress with the recommendation that the committee be continued, with authority to investigate the subject further during the ensuing year.

The work of the committee has been thus far confined to the collection and study of data furnished by public health laboratories in which routine bacteriologic diagnosis of diphtheria is regularly performed. With this object in view, a large number of inquiries and requests for sample outfits were sent out. The information thus collected has been studied with the view of the ultimate recommendation of standard procedures in so far as this is possible. It does not seem desirable, at this time, that a complete culture outfit be recommended for adoption by the Section, or that a standard laboratory technic be outlined. It is deemed advisable, however, to submit a brief summary of the information thus far collected, together with such recommendations as have been agreed on by the committee, and to invite free discussion by members of the Section of the subject-matter presented.

CULTURE OUTFIT

Your committee recommends that the outfit used by state laboratories be so constructed as to be mailable. The present postal regulations require that such an outfit shall consist of two screw-topped metal cases, one fitting inverted within the other, in the inner of which are contained the tubes of infectious matter, protected from breakage by cotton wrappings.

It is further recommended that the culture outfit used in state laboratories shall not contain culture medium, but shall contain swabs only,[1] preferably two in number, enclosed in separate test-tubes for nose and throat cultures. This method eliminates the difficulties and delay arising from the use of old, dried or contaminated culture media, and insures the proper inoculation of the medium by expert hands in the laboratory.

The swabs on arrival in the laboratory should first be used for inoculation of cultures, after which direct smear preparations should be made. All frank positives obtained by the direct smear method (which in expert hands amount to from 60 to 80 per cent. of the total final positives) should be reported at once, and the others should be held for the result of the culture.

Outfits supplied by municipal laboratories may be mailable or non-mailable, as circumstances may dictate, but as mailable outfits are, as a rule, much more expensive, nonmailable outfits are usually to be preferred.

The omission of the culture medium in the outfit designed for municipal use is left optional. It is to be noted, however, that a number of municipalities are now sending out swabs only.

Your committee recommends that all swabs be returned to the laboratory irrespective of the presence or absence of culture medium in the outfit. For this reason, swabs should be sent out in sterile glass tubes plugged with cotton. The swabs so returned are more certain of proper sterilization and are available for direct smear examination and for reinoculation of the culture medium in case of doubtful diagnosis.

Of the materials used for swab sticks, wood, aluminum wire or iron wire seem preferable. Copper or brass wire is not recommended, as there is a possibility that copper salts derived from the oxidation of the wire may, at times, exert an antiseptic influence on the organisms with which the swab is impregnated.

Tongue-depressors are omitted from the outfit by the majority of laboratories.

Drying of the culture medium is prevented in various laboratories by the use of rubber caps, paraffin, sealing wax, aluminum foil and paraffin, and corks enclosed in cotton and dipped in paraffin. In case the aluminum salve box is used a rubber band or strip of physicians' adhesive tape will serve the purpose.

INSTRUCTIONS AND PRINTED MATTER

It is recommended that information as to the interpretation of findings be enclosed in the outfit. This is intended to save the laboratory unnecessary, irrational complaints and to guard against misinterpretation of results on the part of those unfamiliar with laboratory diagnosis. A sample statement of such information is herewith submitted:

> A positive report cancels all previous negatives on the same case.
>
> A negative report may mean any one of the following:
>
> 1. Absence of *B. diphtheriæ* in the throat.
> 2. Failure to reach the bacilli with the swab. This occurs frequently in laryngeal cases and may occur in pharyngeal cases through imperfect technic. (See instructions.)
> 3. Failure to inoculate the medium properly.
> 4. A very few diphtheria bacilli in the presence of many other varieties may be overlooked by the bacteriologist. Statistical study shows this to be infrequent.
>
> "Suspicious organism" calls for a second culture. Antitoxin should be given at once and temporary isolation instituted. All suspicious cultures will be reincubated and will be reported a second time if more definite findings are obtained.
>
> "No growth" means nothing. Diagnosis is withheld and a second culture is required. It may be due to—
>
> 1. Use of an antiseptic in the throat previous to taking the culture.
> 2. Failure to inoculate the medium properly.
>
> "Contamination" means nothing. Diagnosis is withheld and a second culture is required.

It is further recommended that the report of the laboratory cover the following findings only:

B. diphtheriæ present.
No *B. diphtheriæ* found.
Suspicious organism.
Streptococcus (when the predominating organism).
B. influenzæ (when the predominating organism).
Spirillum of Vincent.
No growth.
Contamination (when sufficient to invalidate the diagnosis).

Sample instructions for making throat cultures are also included herewith. (See accompanying sheets.)

RECOMMENDATIONS AS TO POLICY

It is recommended that two successive negative cultures, taken at intervals of not less than twenty-four hours be required for release from quarantine.

It is further recommended that all terminal cultures be taken from both the nose and the throat.[2] The taking of nasal cultures for initial diagnosis is left optional with the physician.

In case of doubtful laboratory findings, temporary isolation of the patient should in all cases be ordered and maintained until a subsequent culture proves negative.

LABORATORY PROCEDURE

Under this heading the committee makes no definite recommendations, but merely submits information as to the customary procedure in public health laboratories. The culture medium in common use for diagnosis of diphtheria is Loeffler's blood-serum. For its preparation horse-serum, pig-serum and ox-serum are used according to the following formula:

Serum	3 parts
Broth, containing 1 per cent. dextrose and 1 per cent. peptone	1 part
Glycerin	4 to 5 per cent.

Some laboratories are still using fractional sterilization on three to four successive days, but the majority are now using the autoclave, either with or without previous inspissation. One correspondent recommends egg-medium for emergency use (25 c.c. of physiologic salt solution to four eggs sterilized in the autoclave or fractionally in an Arnold sterilizer).

---

* Read in the Section on Preventive Medicine of the American Medical Association, at its Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Slack, Arms and Wade: Longevity of *B. Diphtheriæ* on Swabs, Jour. Am. Pub. Health Assn., 1910, xx, 639.

[2] Nose and throat cultures should be taken with separate swabs to avoid transferring the infection from one cavity to the other. In release cases, if desired, both swabs may be rubbed on one and the same culture-tube or box. In diagnosis cases separate culture-tubes should be inoculated from each swab.

The temperature commonly recommended is 37 C. The time of incubation varies from six to twenty-four hours, and in most instances falls between twelve and eighteen hours.

Loeffler's methylene-blue is the sole staining agent recommended by the majority of correspondents and Grübler's preparation is universally recommended as a satisfactory brand.

A few special stains are mentioned, e. g., those of Gram, Neisser, Grouch, Rush and Epstein, as aids in the case of doubtful diagnosis. Of these the one last mentioned appeals to the committee because of its simplicity. The directions are as follows: Stain the slide in the ordinary way with Loeffler's methylene-blue; flood half the slide with Gram's iodin solution. Wash in water and examine. The stain brings out the granules, which are colored blue. The body of the bacillus stains brown.

As to the Wesbrook types, the majority of correspondents report that they are a satisfactory basis for diagnosis for twenty- and twenty-four-hour incubation periods. Two observers report them unsatisfactory in a few instances. All are agreed that the Wesbrook classification is of no diagnostic value for five- or eight-hour incubation periods when the organisms are stained in the ordinary way with Loeffler's methylene-blue.

The virulence test is made in some laboratories in cases of prolonged quarantine, and in a few instances on non-sick carrier subjects. One state institution conducts virulence tests of the organisms in all cases in which the duration of the quarantine is thirty days or over. Another conducts the test after five weeks. The isolation of the organism in pure culture is obtained by streaking on blood-serum. The animal used is commonly the guinea-pig. Death of the animal within four days after a subcutaneous inoculation, with localized necrosis at the sight of injection and successful recovery of the organism, is considered a positive test.

COMMITTEE ON THROAT CULTURES

AMERICAN MEDICAL ASSOCIATION

Sample Directions for Culturing

(Outfit contains two swabs in one test-tube and one culture-tube or culture-box.)

Throat Culture.—No local antiseptic application should be made for at least two hours previous to taking the culture. The patient's throat should be cleared of any adherent food particles, etc.

1. Have the patient in good light.
2. Rub the swab thoroughly against any membrane, exudate or inflamed area in the throat, revolving the swab in the fingers in such a way as to bring it thoroughly in contact with the suspected area.
3. *Do not lay the swab down* or allow it to touch anything other than the surface of the serum.
4. Insert the infected swab into the serum-tube and rub it gently back and forth over the entire surface of the serum, revolving the swab so as to bring it thoroughly in contact with the serum. Do not break the surface of the serum by pushing the swab through it. Do not use the medium if it is dry or contaminated.
5. Replace the infected swab in its own tube and replace the cotton plugs in both tubes.
6. Directions for sending to the laboratory.

Nasal Culture.—Cultures for release must be taken from both the nose and throat in all cases. Use one of the two swabs in the outfit for the nose and the other for the throat, rubbing both swabs on the same serum. Cultures for diagnosis may be taken from the nose alone or from the throat alone. If it is desired to take cultures for diagnosis from both the throat and nose, use a different serum-tube for each.

1. The physician should stand behind the patient, who should preferably be in a sitting posture.* Place the left hand on the patient's chin and hold the head firmly against the body of the operator. With the right hand insert the swab about one-half inch upward into the right nostril. Then raise the hand so that the shaft of the swab is parallel to the floor of the nose and with gentle rotation pass the swab back to the posterior pharyngeal wall. Withdraw the swab and repeat the process in the other nostril.
2. *Do not lay the swab down* or allow it to touch any object other than the surface of the serum.
3. Insert the infected swab into the serum-tube and rub it gently back and forth over the entire surface of the serum, revolving the swab so as to bring it thoroughly in contact with the serum. Do not break the surface of the serum by pushing the swab through it. Do not use the medium if it is dry or contaminated.
4. Replace the infected swab in its own tube and replace the cotton plugs in both tubes.
5. Directions for sending to the laboratory.

Therapeutics

OBESITY

The first question to be considered in connection with this subject is what should be considered an excessive degree of fatness. This can be determined with a fair degree of accuracy for practical purposes from a consideration of the weight of the entire body. The weight of the bones, the muscles, and the viscera constitutes a nearly definite, but of course not exact, proportion of the weight of the whole body. The fluctuations in the same body during the different periods of life are mainly dependent on the increase or diminution in the amount of fat. It has been estimated that the proper weight of any individual may be determined by multiplying his height in inches by 2½. His minimum weight should not be less than twice the number of inches in his height, and his maximum weight should not exceed three times the number of inches in his height. Suppose, for example, a person 5 feet 8 inches in height; his minimum weight should not be less than 136 pounds, and his maximum weight not more than 204 pounds, while his ideal weight would be 170 pounds. But it must be remembered that the average weight varies in different decades, and many would consider these figures too high. Furthermore, it has been estimated that the fat of the whole body should constitute about 1/15 to 1/20 of the whole weight of the body. These figures give a fair index of when treatment should be undertaken.

Excessive fatness is seen in different kinds of subjects. First, there is the overfat person who is descended from ancestors one or more of whom have been unusually stout. That the tendency to fatness is frequently hereditary is indisputable, but it is difficult to understand why a special facility in the conversion of food into fat and its deposition in the body should be transmitted from parent to child. Second, there is the person who eats and drinks more than is necessary for his well-being, and yet who is apparently in good health aside from his fatness. Third, there is the person who eats more than is necessary, who exercises very little, and is anemic and has poor circulation and a weak heart.

The fat of the body is, theoretically, food which is changed into fat and is stored in convenient parts of the body to be used later on when necessity arises. Fat is the form in which reserve energy is stored in the body. It is believed that the chief source of the deposits of fat is the fats, the starches, and the sugars taken into the body as food, but it is probable that under certain conditions a part of the fat is formed from protein.

Undoubtedly the most common causes of acquired fatness are excessive eating, or the eating of excessive amounts, especially of foods rich in fat, sugar and starch. The habitual use of alcoholic drinks, especially of beer and ale, also promotes fatness, because they stimulate digestion and consequently assimilation. Furthermore, the alcohol furnishes material for oxidation, so that less of the tissues of the body undergo oxidation and removal.

An inadequate amount of exercise is another important contributing factor to this condition. Abundant exercise promotes oxidation and uses up a part, at least, of the surplus food which is ingested. People of sedentary habits ordinarily have a weak circulation, and this furthermore predisposes to sluggishness of the metabolic changes, lessened oxidation, and consequently increased deposition of fat.

The physiologic changes connected with the reproductive system are often attended by changes in the amount of fat in the body. Many children put on a large amount of fat during the second decade of their lives. Toward the end of this decade many of them lose a part at least of this excessive development. This is more apt to happen with boys than with girls. In the latter if the menstrual function is not established at the usual time and does not take place in a normal physiologic manner, the fatness often continues into and through adult life. In a somewhat similar way, after middle life, after the menopause in women in particular, and in men after castration, the weight is gradually increased, due to an excessive deposition of fat.

The excessive amount of fat present in the body is usually deposited about the breasts, shoulders, neck, and limbs in young people, while in older people it is deposited in the wall of the abdomen, around the hips, in the large omentum, and around the various abdominal and thoracic organs. Obesity occurs in children, but is most frequent in adults, in whom it is especially likely to make its first appearance toward middle life. It is rarely seen in very old people.

It is scarcely necessary to enumerate and describe the various systems of treatment which have been proposed and recommended for the cure of obesity. In undertaking the treatment of an obese patient, as in the treatment of all conditions, the first thing to do is to get a complete history. It should go without saying that the heart and lungs should be examined, and a thorough examination should be made of the urine. But special inquiry should be made of patients who present themselves for treatment for obesity in regard to the number and frequency of meals, and the food habitually taken at each meal; whether food is taken between meals; whether the food taken at meals is thoroughly chewed; whether it is eaten moist or dry; whether much fluid is taken with the meals, or between the meals; whether the patient takes exercise, when and how much he takes; and how willing he is to put himself to some inconvenience and perhaps discomfort to remedy his condition. Next the heredity should be discussed, and the age at which the weight began to increase above normal.

The next point to consider is, what result should be hoped for or should be aimed at in the treatment of the patient. By very great limitation of the diet the weight may be decreased rapidly, but a decrease in weight greater than two pounds in each week is not desirable, and is likely to be followed by dangerous results to the patient. While the patient is under treatment, his weight, with uniform clothing, should be taken and recorded every week, and the measurement of the circumference of his abdomen should be determined.

It is customary to consider the treatment of this condition under three heads: first, the diet; second, the exercise; and third, the medicine. Naturally the diet is considered first, as that is the foundation of the condition and of its cure. Various writers have given widely different advice in regard to what food should be allowed and what food should be forbidden.

Some have advised an exclusive milk diet in the treatment of obesity. This is not difficult to prescribe if the patient has confidence and is willing to follow the advice. While taking it the patient should be confined to bed, and should drink from two to three pints of milk a day. This treatment should not be continued for more than from five to ten days at a time, but may be repeated at intervals of two or three weeks. In many instances it has given very good results, but should not be advised unless the patient is under the constant observation of the physician.

The exclusively vegetable diet has been recommended by some writers. A strictly vegetable diet may be maintained for from four to six weeks, and then a small amount of meat may be allowed on alternate days. But a too restricted diet is usually not desirable.

While some allow the use of fat, it is fair to presume that the fat taken with the food forms the material most ready for transformation into fat in the body. Unless one disbelieves this, he will naturally advise his patient to abstain from fat of all sorts in his food. Cream, butter, the fat of pork, including bacon, and the fat of various forms of meat should be avoided. In regard to carbohydrates, the starches and sugars, these must be used in limited amount. It is better to reduce the sugar to a very small amount. Some advise forbidding it entirely and using saccharin in place of it for sweetening the food, but the utility of this course is, to say the least, questionable, and it is probably better to allow a limited amount of sugar for sweetening various articles of food which are habitually seasoned in this way. Starches should be reduced, but not entirely forbidden. If the history has been carefully taken, it will be learned whether the patient uses much potato or much bread. As these are the articles of diet which contain the greater part of the starch used, it will generally be found wise to diminish whichever of these two articles of food is chiefly used by the patient. It is in regard to the starches, sugars, and fats that the chief reduction in the amount of food taken should be used, but other foods should also be used in moderation, and particularly meat and eggs.

Much may be accomplished toward the reduction of the total amount of food taken by a regulation of the meals. In the first place, the taking of food between meals should be forbidden, and also evening lunches after the theater or before going to bed. The meals should be strictly limited to three. The breakfast, being with a large proportion of people a light meal, should be maintained in this way. As an example, for breakfast some fruit, as an orange or an apple, one or two eggs, with two not large pieces of bread or dry toast, and a glass of milk, or a cup of tea or coffee with a little milk and a very little sugar. Whole wheat bread or graham bread is less objectionable than white wheat bread. The other light meal is preferably taken at night, and should consist of a light supper, as for instance: a small piece of cold meat, one or two pieces of stale bread or dry toast, a salad of tomatoes, lettuce, or celery eaten without an oil dressing, and a glass of milk or a cup of tea or coffee, as at breakfast. The heaviest meal, the dinner, then, should be taken shortly after noon. It may consist of a light, watery soup, without the addition of flour and without any fat; meat or fish (fresh or salt) in moderation; potato; no bread; the various vegetables such as cabbage, spinach, cauliflower, turnips, carrots, parsnips, string beans; salad made of the various green vegetables which are in season; and a dessert of fruit such as strawberries in their season, peaches, oranges, grapefruit, apples, pears, and melons. The amount of liquid ingested with the food should be limited. All kinds of alcoholic liquors should be avoided. If the patient insists on taking an alcoholic drink, the least harmful are whisky and a sour wine like claret. It is perhaps wiser to allow no fluid with the meal, but to allow a single glass after the meal. Patients will eat less and will chew their food more thoroughly if they do not intersperse the mouthfuls of food with mouthfuls of drink. It is probably wise to limit the entire amount of fluid taken in the twenty-four hours to six glasses; one glass taken shortly after each meal and the others from half an hour to an hour before the meal. Taking the glass of water before eating will lessen the appetite and be the means of the patient taking less food. If the patient is lithemic, more water is indicated.

It is important in prescribing different articles of food to consider the matter of the patient getting a sufficient amount of bulk in the food to cause the more or less agreeable feeling of distention in the stomach which generally leads one to think of ceasing to eat more. If a person is so stout as to suffer discomfort from the condition, it is a matter which should arouse the sympathy of the other members of the family, and they should be willing to submit to the slight inconvenience of having the food for the whole family arranged somewhat with reference to the person who is undergoing treatment. If this can be arranged it will greatly simplify the treatment and make it much less irksome.

The majority of people who suffer from obesity take too little exercise. The history of the patient will have shown to what extent this is true with the individual under consideration. It is necessary to find, if possible, some exercise which the patient will take systematically and continuously and which will not be too irksome. Practically the best exercise is walking. If the patient is not used to walking at all, he should commence walking a short distance several times a day. The exercise should not be carried to the point of undue fatigue. It should be taken after each meal, and should be gradually increased so that the patient walks six or eight miles a day. It may not be practicable to divide this equally among the three periods after eating, but the aggregate should be about up to that amount. The walking should not be a leisurely saunter, but should be a brisk, business-like walk; and the patient should not divest himself of too much of his clothing, because one thing to be sought by the walking is a moderate degree of perspiration. It is rather better to take the exercise after eating than before eating, because if taken before eating the patient's appetite will be so increased that he will desire an unusually large amount of food, instead of being satisfied with an unusually small amount.

Cold bathing is an excellent adjunct to the exercise by walking. It should be followed by a vigorous rubbing, which not only exercises the muscles, but promotes the circulation.

In warm weather swimming is a most admirable form of exercise, combining both the exercise of the muscles and the advantages of bathing. The warm bath is frequently recommended, but is far inferior to the cold bath in usefulness. The Turkish bath has been frequently recommended, but it is of little value, as it simply causes exudation of water from the body which is promptly replaced from the tissues or by the fluids swallowed.

If walking and bathing systematically are impracticable, much benefit may be obtained by systematic calisthenic exercises. These should involve especially the muscles of the legs, hips and abdomen, and should consist of various movements of flexion, extension and rotation. It is not easy to persuade patients to follow these with regularity, but if they are used in this way they are exceedingly efficient.

Drugs come last, and are of the least efficiency. Phytolacca has been recommended as a drug which has a specific influence on the deposition of fat, for it was observed by someone many years ago that birds who ate phytolacca berries were entirely devoid of fat. For this reason preparations of the phytolacca berries have been tried in obesity, but reports of its favorable action are few and inconclusive.

The use of various mineral waters has been highly commended by some writers in the treatment of this condition. Cathell has especially praised the taking after each meal of a glass of Kissingen water, alternating daily with Vichy water. He believes that this has some specific action on the metabolism of fat so that it is not deposited in excess. Cathartics have been used, especially the saline cathartics, with the idea that in this way the amount of food assimilated might be diminished, but this sort of treatment is liable to result in damage to the patient.

Unquestionably the secretion of the thyroid has an important relation to the deposition of fat. A diminished secretion of this gland is commonly accompanied by a tendency to fatness, and an excessive secretion often tends to produce emaciation. Hence it has been proposed to administer the extract of thyroid to patients who were too fat. The dose ordinarily recommended is 3 grains, two or three times a day. In many cases this has seemed to produce favorable results, but it must not be continued too long, and its action must be very carefully watched, so that it may be discontinued as soon as unfavorable symptoms appear.

What has just been said in regard to the treatment of obesity has had reference to robust, well-nourished people who are fat. When the patient is fat, but feeble and anemic, it is necessary to bear in mind certain considerations which must influence the treatment. If the patient is anemic, iron should be systematically administered, and will frequently prove very beneficial in improving the general condition, although of course it will not have any special effect on the obesity.

If the circulation is feeble and the heart weak, it will frequently be advisable to prescribe digitalis to improve the strength of the heart and the force of the circulation.

In regulating the diet it is necessary to avoid reducing this below the needs of the body for nourishment, and especially should caution be observed in reducing the amount of protein taken.

A few points of practical importance it is well to remember are the following:

1. The last meal of the day should be light because there is likely to be less demand made on oxidizable tissues during the night.

2. In prescribing a diet it is necessary to remember and include a sufficient amount of nourishment to maintain the strength of the patient.

3. While water does not materially increase the deposition of fat, if taken with meals it is likely to lead to excessive eating.

4. In arranging the diet consideration must be given to obtaining a considerable bulk of ingested material without at the same time taking an excess of the nutritious elements of food.

5. Alcoholic stimulants should be entirely prohibited.

6. Exercise should be carefully and specifically prescribed, preferably in the form of walking or swimming.

7. The patient should be regularly weighed and measured, so as to determine the results which are being obtained.

8. A diminution in weight should not be effected too rapidly.

9. In prescribing both medicine and food care should be taken to avoid bringing on indigestion, and with it serious impairment of nutrition.

10. The object of treatment is to maintain normal nutrition, and at the same time to avoid overnutrition.

SATURDAY, SEPTEMBER 16, 1911

HEATING AND VENTILATION

It has long been the custom of hygienists to insist that ventilation or perflation of crowded rooms is necessary in order to remove poisonous emanations arising from the human body. More than twenty years ago, however, observations made to determine the nature of the alleged poisonous properties of the expired air and of "crowd poison" led to negative results. No toxic organic constituent could be demonstrated in the air of crowded rooms, and as for the carbon dioxid, it was so relatively slight in amount that it could not be held responsible for the physiological effects observed, and could at most be regarded as "a measure of danger." To what, then, are due the disagreeable consequences of remaining in an overcrowded, poorly ventilated room? There can be no doubt that such consequences are real and not imaginary, and that they range all the way from slight depression and headache to severe nausea, vomiting and collapse.

The answer to a question that has caused much perplexity seems to have been given by various physiologic experiments of the last few years. To put it briefly, the whole trouble seems to be due to a disturbance of the normal thermal relations of the body. It is a common observation that the depression and fatigue experienced on a hot, humid August day are very similar to the feelings that develop in a crowded "close" room. The cause is apparently the same in both cases, namely, interference with the normal rate of loss of body heat. At least three atmospheric factors may be concerned in such interference: high temperature of the ambient air, high moisture content and lack of air movement. Paul[1] kept healthy persons for several hours in a close cabinet until the carbon dioxid rose to 100 or 150 parts per ten thousand—more than ten times the amount usually stated as "allowable"—but so long as the temperature and moisture content were kept low no symptoms of illness or discomfort developed. Other experimenters have reached the same result by simply having electric fans whirled in such an experimental cabinet. The motion these imparted to the air was sufficient to facilitate a normal, physiologic loss of heat from the body in spite of high temperature and humidity. Similar cabinet experiments in which the subject was enabled to breathe the fresh outside air through a tube, but was otherwise subjected to the conditions of a close room, likewise showed that the symptoms attributed to "bad ventilation" are in nowise due to poisons excreted in the breath. The upshot of all such experiments is that it is not the chemical constitution of indoor air that is injurious, but the overheating, the stagnation and sometimes the moisture content.

Among the more important recent papers dealing with this question may be mentioned especially an article by Crowder[2] on the ventilation of sleeping-cars. In addition to an admirable critical summary of the experimental evidence on the subject the article contains valuable data from the writer's own study of car ventilation. Much of the discomfort experienced by sleeping-car travelers is undoubtedly due, as Crowder suggests, to overheating and not to insufficient air-supply. Important practical results may be looked for in the field of ventilation as soon as engineers come to realize and to apply the knowledge gained by hygienists in the past few years. We are likely to hear less about "impure air" and more about stagnation and overheating.

All this does not, of course, mean that there is no harm in crowded rooms or that the open-air treatment of tuberculosis is based on false assumptions The investigations cited merely substitute the right for the wrong interpretation of observed facts. Bodily resistance, as bacteriologists have shown us, may be lowered by a variety of factors. It might conceivably be diminished by the inhalation of "crowd poison," or by interference with the heat regulation of the body. The latter seems to be the true explanation of the undoubtedly injurious effect of overcrowded rooms. So far as tuberculosis is concerned, the predisposing effect of damp houses and damp climates is well known. The experiments recorded by the investigators mentioned above suggest that there are as yet undeveloped possibilities in the control of indoor climate. Precise knowledge of the factors concerned in producing the bad effects of overcrowding is the first step toward a scientific remedy for the condition.

CHLOROFORM FOR THE DISINFECTION OF TYPHOID CARRIERS

The sanitary problem presented by the so-called "typhoid carrier" is one of great difficulty, and any steps leading toward its solution merit special consideration. For this reason, a recent article by Bully[1] on the disinfecting power of chloroform on typhoid infections of rabbits is of interest, although as yet it appears to have little practical applicability. The work of Bully is in large part an experimental review of a previous investigation by Conradi.[2] The latter started with the assumption that chloroform, or similar lipoid-solvent narcotics, should have a special affinity for cell and bacterial lipoids, and by virtue of this should be able to penetrate and destroy intracellular bacteria. Experimental work on animals confirmed this assumption, and later work by Hailer and Rimpau[3] lends it strong support, as does that of Bully. Bully's method consisted in inoculating rabbits intravenously with a culture of typhoid bacilli, and in following this with daily rectal injections of 0.5 c.c. of chloroform, in emulsion, for variable periods, at the end of which the animals and their controls were killed and examined bacteriologically. In all, the experiment was carried through on forty-two animals, with forty others serving as controls. The chloroform injections were begun at various intervals after the inoculation, and were kept up for periods ranging to a maximum of ten days. Of the forty-two animals so treated, five (15 per cent.) could be shown still to contain living typhoid bacilli. Of the forty control animals, nineteen (48 per cent.) were still infected. In all cases in which the organism was recovered, it was found in the bile; occasionally, but much less frequently, in the spleen as well.

---

[1] Paul: Ztschr. f. Hyg., 1905, xlix, 405.

[2] Crowder, Thomas R.: Arch. Int. Med., 1911, vii, 85.

[1] Bully: Ztschr. f. Hyg. u. Infektionskr., 1911, lxix, 20.

It is evident that the administration of chloroform had definite effect on the disinfection of the animals. But the dosage, approximately one four-thousandths of the weight of the animal is for a substance like chloroform relatively enormous. Calculated for a man of average weight (70 kg.) such an amount would mean the daily administration of almost 18 gm., or over half an ounce, of chloroform—altogether too large a quantity to be given with assurance of safety. The experiment has been tried of giving human typhoid carriers chloroform in more moderate doses—up to 2 c.c. daily—without any appreciable effect on the typhoid bacilli in their stools.

While in all probability chloroform itself is too toxic for use as a disinfectant of chronic typhoid infections, possibly other substances of the same general class may be found that will be active within the limit of safe dosage. It is almost too much, however, to hope for the finding of any disinfectant capable of freeing the body of the organisms without itself having some injurious action on the host.

CHEESE AS A FOOD

Important observations regarding the food value of cheese, and its cheapness by comparison with some other dietary staples, are to be found in a government report,[1] which details exhaustive experiments made not only in artificial digestion, but also with human subjects, the office of experimental stations of the Department of Agriculture cooperating. The Cheddar or American cheese in various stages of ripening was studied, as were also some foreign kinds of cheese. From this publication we learn there is no warrant for the popular theory that cheese, even when green or unripened, is difficult of digestion; or that unripened cheese, or cheese in any stage of ripening, is constipating. There is a marked difference in the physical characteristics of the cured and green products; the water-soluble material in well-cured cheese is high, while in the uncured product it amounts to almost nothing; no doubt these evident physical and chemical differences have been largely responsible for the popular and established misconception above stated. The milk solids are very digestible and make an almost perfect food. With the addition of rennet, and the development of lactic acid in cheese-making, some chemical changes take place; but it is rather difficult to explain why these should transform digestible solids in milk into indigestible solids in cheese. Nor can the experimenters understand why any sort of cheese, green or otherwise, should tend to constipation; the cause of the idea is probably that many people are fond of the mild-flavored curd and eat large quantities of it when it is constantly at hand. The digestive disturbances attributed to peculiarities in the cheese itself are probably due merely to over-eating, or to the custom of eating cheese only at the close of the meal, when one has already had more than enough food.

Skim-milk cheese, when sold as a whole-milk product, is a fraud that is a positive injury to the dairy business; but skim-milk cheese, stated and sold as such, is entitled to consideration by both producer and consumer. It is digestible and has a food value; made to have an agreeable taste it could be sold cheaply to poor people. Cottage cheese is another cheap and palatable product, much of which could be added to the dietary at a great saving in the total cost of food. Indeed, all kinds of cheeses, even the very highly flavored and so-called condimental cheeses, have a high food value.

Cheese contains, in unusually concentrated form, every essential to human sustenance. It has been held by epicures to be a stimulant to digestion, when taken with the salad, or at the end of the meal. But we now learn that it is digestible both as a condiment, and as the chief factor in a meal. Many European people eat largely of cheese, either by itself, or sprinkled on vegetables, or cooked with other food. Here, as in some other matters, America may learn much from the Continent. The Italians have many foods, such as macaroni, with which cheese is mixed. They have cheese grated and constantly at hand as a flavoring, quite as we use pepper and salt. The Swiss eat largely of cheese, which with bread forms the greater part of the dietary of this very healthy people; and those Swiss farmers who have settled in Wisconsin continue to manifest the athletic attainments and the physical endurance of their forbears. The sensible Germans consume large quantities of the cheap, but highly flavored skim-milk cheese, one popular kind of which is officially credited with "perhaps the most pungent odor of all the varieties of cheese made." The French also have some gorgeously flavored cheeses which the polite ask at table, not to have "passed this way," but to have "directed this way." Nevertheless such cheeses are wholesome; and their flavors are caused by beneficent microorganisms. One may here note the rejoinder to a gourmand who, having devoured some Roquefort, observed that, like Samson, he had slain his thousands and his tens of thousands: "Yes, and with the same weapon."

[1] Doane, C. F.: The Digestibility of Cheese, Circular 166, U. S. Department of Agriculture, Washington, D. C.

The consumption of cheese by the American people should be increased, on the grounds both of economy and of superior food value. A pound of cheese has nearly the same food value as two pounds of lean meat or eggs, or the same weight of ham. In comparing cheese with meat, it should be noted that not only is the former superior in food value as measured by the cost of an equal number of calories, but also it furnishes nitrogen without the accompaniment of purins which will increase the amount of uric acid in the system. For this reason, it may be eaten by those inclined to gouty affections to whom meat is denied.

THE CHARGE AGAINST DR. WILEY

II. THE INDIANA CASE

We continue this week[1] the publication of some of the testimony brought out before the congressional committee which investigated the Wiley matter. This time we deal with the Indiana case, which, as our readers may remember, created considerable talk some years ago. As our readers, of course, know, Indiana has a pure food law and a good one. One of its requirements practically prohibits the sale of foodstuffs preserved with benzoate of soda. Two of the largest catsup manufacturing concerns which preserve their products with this chemical—Curtice Bros., of Rochester, and Williams Bros., of Detroit—finding that their business in Indiana was being injured, attacked the pure food law of that state and attempted to have it declared unconstitutional. These firms naturally wished to present as strong evidence as possible and attempted to have the referee board—which had declared sodium benzoate innocuous—give testimony in their case favorable to its use. As will be seen by the evidence we quote this week, Secretary Wilson sided with these firms and urged members of the referee board to testify in their favor. This they did either by deposition or by personal appearance at the court in Indianapolis—and the United States paid their expenses!

Nor was this all. As is well known, Dr. Wiley also had carried out a series of experiments to determine the harmlessness or harmfulness of sodium benzoate. His work was done before the referee board was created or even thought of; it extended over a longer period of time than that given to the same subject by the referee board and it was, moreover, carried out under Dr. Wiley's personal supervision. As he said at the hearing:

> "I gave personal attention to this work and did not delegate it to other people. I was at the Bureau on the coldest winter mornings long before daybreak to supervise the preparation of the breakfast for these young men and was there late to see that the supper was properly prepared."

As a result of his experiments, Dr. Wiley declared sodium benzoate harmful, a position which he has consistently maintained. Naturally the Indiana state officials in defending their pure food law from destruction, wanted to have his testimony; they also wanted to be permitted to submit to the court the findings of Dr. Wiley in his experiments. Did the federal officials cooperate with the officers of the State of Indiana in the latter's attempt to get all the facts on both sides? No. On the contrary, the Indiana officials had the greatest difficulty in obtaining from the Department of Agriculture Dr. Wiley's data. When Solicitor McCabe learned that they wanted Dr. Wiley to testify, he submitted a decision to the effect that they could not compel the Chief of the Bureau of Chemistry to go to Indianapolis and that if he did go, it would be on his own responsibility. This, of course, was paramount to ordering Dr. Wiley not to give testimony that would support the Indiana pure food law. In fact, as will be seen by the evidence, McCabe admitted that he "did not want Dr. Wiley to testify in this case."

The attitude of Wilson and McCabe in the Indiana case is the attitude they have shown in every case in which the interests of the people and the interests of the manufacturers clashed. We wish we had space to quote all the evidence that was given before the congressional committee; we feel sure, however, that what we do give this week will prove interesting and instructive.

Current Comment

FRANCIS TRUTH—A DIVINE HEALER UP TO DATE

Mr. "Francis Truth," divine healer, has recently been arrested in San Francisco. This is no new experience with him, however, since he has undergone similar experiences at Jacksonville, Denver, New York and no doubt other cities. A brief "appreciation" may, in the circumstances, not be amiss. In March, 1895, a half-page advertisement appeared in newspapers, setting forth the wonderful powers of "Francis Truth." This was not the man's real name, but was assumed as indicating the chief and most resplendent trait of his mellow character; his actual name seems to be N. H. Bemis. There was a portrait of "Truth" gazing calmly upward, as one in the confidence of the Infinite. Above his refulgent countenance, crowned with impressive locks, was pictured "Truth's Temple of Divine

---

[1] Propaganda for Reform Department, p. 991.

Healing," in Boston. To the right were the lame, the halt and the blind who, in great numbers, were coming to the Temple; to the left were those who had just seen "Truth." There was no sickness, no lameness among them now; no tuberculosis, no cancer, no leprosy—nothing but health! Naturally they were happy, and were felicitating one another. Below the portrait were represented the scores of stenographers, who were busy attending to "Truth's" heavy mail, which had been sent him by the suffering and the afflicted. "Truth" stated: "I have cured every disease known to man. Through me He has thought wise to rejuvenate the power of Divine Healing, after it has lain dormant for nearly two thousand years. Perhaps I merited it. I have always led a good Christian life." An enthusiast stated in this advertisement: "What a busy man Francis Truth is! The sacred power of Divine Healing which has been intrusted to him—to one man among the many billions of men—is a mission for the public weal that gives him little time for the society of his wife and baby, whom he loves devotedly." A few months before this "Truth" was working on a salary of some twenty dollars a week. He looked about to see how this could be bettered. It would seem that reports of the large profits being made by medical charlatans stimulated his imagination—an admirable one when it got to work. He set up a healing establishment of his own. Within a few weeks his enterprise assumed the proportions indicated in the advertisement here reviewed. Half-page advertisements, by the way, cost a good deal of money, especially when they are to appear in metropolitan newspapers. Very shortly afterward he was arrested on the charge of using the mails for fraudulent purposes. He pleaded not guilty, and was released on bail. His case came up for trial on July 10, 1900. He retracted his former plea, and changed it to "guilty." On five charges he was fined the maximum penalty for each; he paid the fines—$2,500 in all. He could afford it. Between the times of his arrest and of his pleading guilty over 30,000 letters addressed to him, about all of which were believed to contain money, accumulated in the post office. These were returned to their senders. It would appear that subsequently other communities have been even "easier" than Boston in which to do business of this kind.

CHARITY AND STAMINA

It has often been observed that living organisms require for their fullest development a certain amount of resistance in their environments. The individual or the species for which things are made too easy loses the unused function. The butterfly helped from its chrysalis has imperfect wings; the man fed on soft foods has bad teeth. The parasite is always a weakling and sometimes a degenerate monster. The parasitic dodder, which draws all its sustenance from the sap of the host, is a plant without a root or a leaf. The hermit crab, which, instead of growing a shell for itself like other crustaceans, makes use of the cast-off shells of mollusks, is atrophied in some of its members and enfeebled in its whole organism. So with the intellectual environment and the mental qualities of man. The pauper and the pampered child of wealth are alike deprived of those qualities of initiative and self-reliance on which their respective environments make no demand. Unnecessary charity is twice cursed; it curseth him that gives and him that takes; all of which goes to prove (if proof were needed) that abuse of medical charity is as bad for the public as it is for the profession.

Medical News

CALIFORNIA

Personal.—Dr. Anna M. Flynn, San Francisco, fractured her left leg, below the knee, in a fall of 30 feet down a quarry embankment, August 27.——Dr. Fred T. Bond has been appointed president of the board of health of Vallejo, and Dr. Edwin A. Peterson health officer.

Against Advertising Specialists.—The San Francisco Board of Health has recommended the passage of an ordinance prohibiting medical specialists from advertising. The board declares that: "The claims toward curing diseases which are made by this class of fraudulent so-called practitioners are but a lure to attract the innocent and inexperienced."

Permanent Home for Society.—At the meeting of the Board of Councilors of the Los Angeles Medical Association, July 17, a resolution was adopted, providing for the formation of a separate committee to be known as the Permanent Quarters Committee to have control of the funds set aside for permanent quarters for the association. The committee consists of the president and secretary, exofficio, and Drs. H. Bert Ellis, Los Angeles; Fitch C. E. Mattison, Pasadena, and Walter Lindley, Los Angeles. The association has already a nucleus in the form of a term deposit of $803.56.

ILLINOIS

Report on Health of Employees.—The manufacturing department of the Pullman Company is said to be the first of the large employers of the state to comply with the new occupational disease act, and file its report with the State Board of Health. The report shows that of 433 employees, 378 were healthy.

Personal.—Dr. Perry H. Wessel has succeeded Dr. August H. Arp, resigned, as health commissioner of Moline.——Dr. Emerson M. Brewer, Rantoul, has been appointed district physician for the Illinois Central System.——Dr. Tyler Meriweather, has succeeded Drs. Cassidy and William J. Chenoweth as local surgeon for the Illinois Central system at Decatur.——Dr. Harvey L. Hensley, Oakwood, who has been seriously ill with typhoid fever in Minnesota, has returned home.——Dr. A. Albert Absher, Sibley, had three ribs broken by the overturning of his automobile, August 30.——Dr. J. K. Egbert, Sycamore, has sailed for Europe.

Chicago

Medical Esperanto Association.—The American Medical Esperanto Association (American Esperanto Asocio Kuracistoj) has been incorporated by Drs. Jacob Frank, Isaac J. K. Golden, Paul Gronnerud and others, to promote the study of Esperanto.

Personal.—Drs. Ludvig Hektoen and Anton T. H. Holmboe received the honorary degree of doctor of medicine, in connection with the centennial jubilee of the University of Christiania, September 8.——Dr. and Mrs. Philip F. Shaffner have returned from Europe.

How To Keep Well.—Under this title Dr. William A. Evans, formerly health commissioner, is conducting a department of public health daily in the *Tribune*. This department is devoted to the dissemination of information as to right living and to the stimulation of public interest in the subject.

New Head of Tuberculosis Institute.—James Minnick has been elected superintendent of the Chicago Tuberculosis Institute and secretary of the Illinois State Association for the Prevention of Tuberculosis. Plans will be worked out at once for the organization of local societies, the preparation of a traveling exhibit, and the examination for tuberculosis of employees in manufacturing establishments.

Free Serum.—The health department has announced that it is prepared to furnish antirabies serum free to all persons whose circumstances will not permit them to pay for the treatment in private institutions. The serum comes from the government laboratories at Washington. Physicians should send patients requiring this treatment to the Iroquois Memorial Hospital, 23 North Market Street, where they will be examined by the city's physicians and the health department notified. Individuals who have been bitten by dogs supposed to be mad will also be admitted to the hospital without direction from physicians.

INDIANA

Tuberculosis Cottage Dedicated.—The cottage at the Boehnue antituberculosis camp, Evansville, built and furnished by the local camp of the Woodmen of the World, was dedicated with appropriate ceremonies August 27.

Personal.—Dr. S. Kenosha Sessions, formerly a member of the staff of the Southern Indiana Hospital for the Insane, Evansville, has been elected superintendent of the Indiana Girls' School, Clermont.——Dr. Orion E. Maddox, Rockville, is reported to be seriously ill with ptomain poisoning.

City Takes Charge of Isolation Hospital.—At a meeting of the city council of South Bend, August 28, an ordinance was unanimously passed embodying the agreement between the commissioners of St. Joseph County and the city board of health, relative to turning the county isolation hospital over to the city. The agreement specifies that the city must provide a caretaker to be constantly on duty in the hospital, that patients from any part of the county shall be received at the hospital, and that no discrimination is to be shown in the treatment of the patients from different parts of the county.

Society Makes Recommendation Regarding Hospital.—The Knox County Medical Society at its August meeting made the following recommendations regarding the management of the Good Samaritan Hospital, Vincennes: That a medical superintendent be appointed, to be selected by the society and approved by the board of directors of the hospital; that he serve for a term of one year and be given the authority to appoint the head nurse; that he superintend the purchase of all medical and surgical supplies and appliances; receive and adjust all complaints, and that he be dean of the training school with full power to organize and superintend the same, and that the free use of the hospital be extended to the members of the society and their families.

IOWA

Personal.—Drs. J. Rea, William C. Kasten, John R. Walker, Charles F. Wahrer and France C. Roberts have been appointed by the Fort Madison Medical Association a committee of maintenance for St. Elizabeth's Hospital after the expiration of the term of the present board, September 15, until the Sacred Heart Hospital, now in course of construction, is ready for use.——Dr. William M. Morton, Iowa Falls, has moved to Southern California, and will be succeeded in practice by his youngest son, Dr. G. M. Morton, Marshalltown.

MARYLAND

Tuberculosis Dispensary Opened.—A dispensary for the free examination and treatment of persons afflicted with tuberculosis was opened in Federated Charities Building, Frederick, September 1. All the physicians of the city have offered their cooperation, and it is the intention of the local association to wage a vigorous fight against tuberculosis.

New State Hospital.—Sylvan Retreat, the Allegany County institution for the insane, is to be made a state hospital for the Western District of Maryland, embracing Washington, Allegany and Garrett counties. The institution has 102 inmates, of whom fifty-three are women. Eventually it is proposed to enlarge the hospital, creating male and female departments with industrial workshops.

Baltimore

Dr. Kelly Convalescent.—Dr. Howard A. Kelly, who was operated on recently in Rochester, Minn., is reported to be doing very well. Dr. Kelly had suffered from "dyspepsia" all his life, and recently the attacks became more acute, so that, while he was in camp, he decided to go at once to Rochester, Minn., where Dr. William J. Mayo operated, finding a badly-infected gall-bladder, with dense adhesions, especially of the duodenum, requiring two drainage tubes.

Personal.—Dr. Don P. Peters, for three years resident physician at the Church Home and Infirmary, has resigned and has been succeeded by Dr. Eugene Wright.——Drs. Harry Friedenwald and Joseph E. Gichner have returned from Europe.——Dr. Harry W. Stoner has recovered from a serious attack of septicemia.——Dr. Lewellys F. Barker sailed for Europe, September 2.——Right Rev. Luther B. Wilson, M.D., has returned after an absence of nine months in Africa, fully recovered from a fever which had lasted nearly ten weeks.

MICHIGAN

Medical Books Transferred.—On account of the overtaxing of the capacity of the Detroit public library, about 4,500 of its medical books have been transferred to the custody of the Wayne County Medical Society.

Sanatorium Notes.—Houghton County on August 22 awarded the contract for the construction of a county tuberculosis hospital, to cost $10,000.——Dr. Zell L. Baldwin is said to have been prohibited, by a restraining order, from maintaining a tuberculosis sanitarium in the residence portion of Niles.

Addition to a Hospital.—Ground has been broken for an addition to the Harper Hospital, Detroit, to cost about $400,000. The first building to be erected is to be six stories in height and of steel and cement construction. It is expected that the new addition will be ready for occupancy about Jan. 1, 1913.

Personal.—Drs. George L. Le Fevre and Frank W. Garber, Muskegon, sailed for Europe, August 26.——Dr. Charles L. Grube, formerly health officer of Saginaw, is reported to be seriously ill, as a result of overwork.——Dr. Ansel B. Smith, Grand Rapids, was operated on recently in Ann Arbor for appendicitis.

MINNESOTA

Home from Europe.—Drs. A. Torland, Minneapolis, and William C. Eichler, Underwood, have returned from Europe.

Hospital Dedicated.—Elliot Memorial Hospital, the first building to be completed on the new university campus, and the first and central building in the system of hospital buildings contemplated for the University of Minnesota, Minneapolis, was dedicated September 5.

Society Meeting.—At the annual meeting of the West Central Minnesota Medical Society, held in Morris, August 22, the following officers were elected: President, Dr. Amos Leuty, Morris; vice-president, Dr. J. G. Whittemore, Donnelly, and secretary and treasurer, Dr. Herbert L. Hulburd, Morris.

Association Merger.—At the joint meeting of the Southern Minnesota Medical Association and Minnesota Valley Medical Association, held at Rochester, August 3 and noted in The Journal of August 19, the associations were merged under the name of the Southern Minnesota Medical Association. It was decided that two meetings be held each year, the annual meeting to be held in Mankato, on the third Tuesday in January, and the semi-annual meeting on the first Tuesday after the first Monday in August, at such place as may be determined at the annual meeting. [illegible] were elected to serve until the annua[illegible] Dr. Louis A. Fritsche, New Ulm; first [illegible]n E. Crewe, Rochester; second vice-president, Dr. Hugh F. McGaughey, Winona; secretary, Dr. William T. Adams, Elgin; treasurer, Dr. George F. Merritt, St. Peter.

MISSISSIPPI

Fire in State Hospital.—Fire in the Mississippi Hospital for the Insane, Jackson, damaged the wards for negro inmates, several of whom escaped. Relatively little damage was done by the fire and all the patients were returned to the institution.

Personal.—Dr. and Mrs. Robert A. Strong, Pass Christian, have gone abroad.——Dr. J. E. Bayless, Hattiesburg, has been appointed health officer of Forest County, vice Dr. Lawrence B. Hudson, resigned.——Dr. Donald P. Street, Vicksburg, has been appointed local surgeon for the Yazoo & Mississippi Valley Railroad.

Cocain Use Among Negroes.—The Hinds County grand jury in its final report says: "The sale and use of cocain is alarming, principally among the negroes, who, in some sections of the county, when short of cash, have actually bartered their farm products for the drug. We trust good citizens will continue to assist the officers in rooting out this evil which is demoralizing labor and filling the jails with criminals."

MISSOURI

Personal.—Dr. John Punton, Kansas City, has returned from Europe.——Dr. J. R. Van Atta has been appointed pathologist by the hospital and health board of Kansas City.——Drs. David B. Robinson, Frederic C. Lamar, Fred B. Kyger, Frank C. Neff, William Marsh, Eugene P. Hamilton, James S. Hunter, Clarence S. Capell, Otho L. McKillipp and A. Isidor Anderson have been appointed physicians in the school inspection department of Kansas City.——Dr. Lynn G. Taylor has been appointed a member of the medical visiting staff of the Kansas City General Hospital, vice Dr. Arthur C. Leonard.

NEBRASKA

Ill and Injured.—Dr. George A. Byers, Snyder, sustained a fracture of the skull and other serious injuries by overturning of the automobile between Snyder and Scribner.——Dr. William M. Thomas, Beatrice, is seriously ill with typhoid fever.

New Medical Staff Appointed.—At the annual meeting of the directors of the Wise Memorial Hospital, Omaha, the following medical staff was appointed: Drs. Oscar S. Hoffman, Charles C. Allison, Robert Gilmore, John E. Summers, Byron B. Davis, August F. Jonas, James S. Goetz, Charles W. Pollard, Frank S. Owen, Abraham Romm, Adolph Sachs, Henry B. Lemere and Bernard A. McDermott.

NEW YORK

Personal.—Dr. James W. Russell, first assistant physician at the Willard State Hospital, has been appointed for similar position at the Matteawan State Hospital and Dr. William J. Tiffany, Binghamton, second assistant physician at the Binghamton State Hospital, has been appointed a member of the staff of the Matteawan institution.——Dr. Harley Heath, Albany, has been appointed physician of the Great Meadow Prison, Comstock.——Capt. Charles W. Farr, M. C., U. S. A., retired, Elmira, has been appointed physician at the State Prison, Sing Sing, vice Dr. Fred E. Lettice, resigned.——Dr. Fred M. Meader has succeeded Dr. W. W. White as city bacteriologist of Syracuse.——Dr. George Lenz has been elected president and Dr. E. D. Hagedorn secretary of the medical staff of the Nathan Littauer Hospital, Gloversville.

New York City

Dinner to Italian Physician.—The Italian Medical Society of New York gave a testimonial dinner to Prof. Dr. P. G. Spinelli, professor of gynecology in the University of Naples, September 4. Dr. Spinelli is making a study of hospital conditions in the United States with especial reference to gynecology and surgery.

Personal.—Dr. Theodore C. Janeway has been elected a member of the board of scientific directors of the Rockefeller Institute for Medical Research, vice Dr. Christian A. Herter, deceased.——Dr. J. Conger Bryan is said to have been committed for five days to the psychopathic ward of Bellevue Hospital, September 2.

Glasgow Physician Guest of Society.—On the occasion of the visit to New York City of Dr. Albert A. Gray, Glasgow, a meeting is to be held at the New York Academy of Medicine, September 20, under the auspices of the Eastern Medical Society of New York, which the medical profession is cordially invited to attend.

Reduction of Infant Mortality.—The Committee for the Reduction of Infant Mortality, satisfied with the results of the allied agencies in their warfare against diarrheal diseases this summer, plans now to turn its attention to a demonstration against the deaths of babies due to congenital troubles. Diarrheal or gastro-intestinal diseases cause about 38 per cent. of all infants' deaths. Congenital troubles, however, are second with about 17 per cent. of the total. Remarkable success has been attendant on the efforts against diarrheal diseases this summer as the figures given out week by week from the board of health attest, but in order to reduce infants' deaths to an unpreventable point, other causes must be attacked with equal intelligence. Special attention is now to be paid by the committee to 1,000 mothers who await the arrival of offspring, in an endeavor to bring to bear all of the community's resources which will enable the mothers to give to the world well children, strong enough to combat the many foes which city life has reared to assail them on every hand. An intensive study is to be made of these 1,000 cases preliminary to a genuine campaign along these lines next summer. Already the committee has begun this task and has 500 expectant mothers under the guidance of its nurses. An arrangement has been made with the Russell Sage Foundation which will detail a special nurse to devote all of her time to this work. The number of expectant mothers under guidance will be increased at once by another 500. All of the mothers will first be given a careful physical examination in order to detect disease or other ailments dangerous to the welfare of the coming child. In the meantime, the nurses will be instructing the women in methods of proper care of themselves, preparatory to the coming of children. The beneficial results of exercise are to be pointed out, a proper diet, regularity of sleep and freedom from worry prescribed. Whenever an expectant mother is forced to overwork, help will be provided for her that she may save her strength to give to the coming child. The use of drugs, beer and whisky are strongly advised against. The nurses are to make arrangements for the women to go to hospitals in ample time. If they do not care to do this, a physician is to be provided and proper nursing. No midwives are to be allowed to handle any of the 1,000 cases which the committee proposes to direct. The wishes of nationalities, such as the Italians, who do not like to have men doctors in attendance on confinement cases, will be respected and women physicians provided for them. After confinement rest will be provided for the mothers and the children referred to the milk stations. The babies born will be watched with extreme care during the first month and a careful record of results. Last year about one-third of all infant deaths occurred among children who were not yet 1 month old. The committee will endeavor to prove from the 1,000 cases that this one-third can be materially lowered. If the study prove this to be true an active general campaign will be undertaken next summer along these lines. A circular is also ready to deliver among expectant mothers, giving them information concerning the proposed work and instructing them how they may best give birth to healthy children.

OHIO

City Official Assaulted.—Dr. Sample B. McKerrihan, city physician of Portsmouth, while carrying out his official duties respecting quarantine of a house in which a child was ill with diphtheria, was dangerously wounded by the father of the child, August 22. His assailant has been charged with assault with intent to kill.

Ill and Injured.—An attempt was made, August 28 by an inmate of the Ohio Soldiers and Sailors' Home, Sandusky, to shoot Major John Haynes, chief surgeon of the institution. ——Dr. Louis H. Frechtling, Hamilton, was operated on for appendicitis, August 23, in Mercy Hospital.——Dr. James J. McClellan, Columbus, is reported to be improving.——Dr. John W. Nixon, New Philadelphia, was seriously injured in a runaway accident, August 15.

Personal.—Dr. Charles O. Probst, Columbus, for twenty-five years secretary of the state board of health, sails September 28 for Vienna.——Dr. John C. George, assistant physician at the Dayton State Hospital, has been selected superintendent of the Miami Valley Hospital.——Dr. E. A. Baber, assistant physician at the Dayton State Hospital, has been appointed superintendent of that institution, vice Dr. Arthur F. Shepherd, Dayton, who becomes a member of the State Board of Control of Ohio Institutions.——Dr. Frank McCafferty has been appointed a member of the Columbus board of pension examining surgeons, vice Dr. James U. Barnhill, deceased.

PENNSYLVANIA

Personal.—Dr. Malcolm Z. Gearhart, Reading, who was operated on in Jefferson Hospital for appendicitis, is recovering. ——Dr. Augustine C. Luhr, formerly of Philadelphia, has moved to St. Mary's.

Fourth District Meeting.—About seventy physicians from Lancaster, Lebanon and Dauphin counties met at Mount Gretna, August 30, for the annual meeting and outing of the Fourth Censorial District Medical Society. Notwithstanding the cold and rain which prevailed the members kept up their spirits and the meeting was very successful. The following officers were elected: president, Dr. John B. MacAlister, Harrisburg; vice-president, Dr. Hugh Hamilton, Harrisburg, and secretary, Dr. Dewitt C. Laverty, Middletown. New by-laws were adopted, one of which changes the name of the association to the Association of Physicians of the Fourth Censorial District of the Medical Society of the State of Pennsylvania. Resolutions were unanimously adopted commending Dr. Harvey W. Wiley for his course in the war against adulterated foods.

Philadelphia

Back from Europe.—Drs. Howard F. Hansell, Judson Daland, S. Lewis Ziegler and Harvey Shoemaker have returned from Europe.

Spinelli in Philadelphia.—Dr. Pier Giuseppe Spinelli, professor of gynecology in the University of Naples, Italy, was the guest of honor at a reception given by the Italians of this city, September 8. He remained for a week, visiting the clinics of the various hospitals.

Gifts to Hospitals.—The will of the late Elizabeth C. Reakirt includes contingent bequests of $10,000 to the Children's Hospital under the care of the Ministerium of the Lutheran Church and of half of the residue of her estate to the German Hospital.——Dr. Gertrude A. Walker has given $1,000 to endow a baby's bed in the maternity of the Woman's Medical College Hospital.

Sterilizing Plant for Marcus Hook.—On September 8, the State Quarantine Board awarded a contract to the Kensington Engine Works to install a steam sterilizing and formaldehyd plant at Marcus Hook for $3,305. The plant will be able to sterilize 200 blankets at one time.

Typhoid Checked.—Typhoid fever in the Twenty-Second and Thirty-Second wards has been traced to the infection of milk from cows that were watered in polluted streams. The cases in the Thirty-Second Ward caused the city authorities much alarm as that section of the city is supplied with unfiltered water. Investigation showed, however, that the water while cloudy contained no infection. The residents of this section have presented a petition to city councils demanding that the work on the Queen Lane filter plant be rushed to completion.

SOUTH CAROLINA

Personal.—Dr. Morris J. Alexander, Tunica, has been appointed clinical assistant in pediatrics in the Medical College of Virginia, Richmond.——Dr. Frank B. Sanders, Hagood, has been appointed physician to the Minnesota state reformatory, St. Cloud.——Dr. A. M. Wylie has been appointed city physician of Chester.

TENNESSEE

Health Talks in Nashville.—The Public Health Department of the General Federation of Women's Clubs announces the following topics for use by all federated clubs in Nashville and by the organizations of women which desire to cooperate: October, "Community Health: Know-Your-City Campaign;" November, "Social Hygiene: Education in Home and School;" December, "Tuberculosis: Ventilation and Fresh Air;" January, "Mouth Hygiene: Tooth Inspection Day;" February, "Clean Food: How and Where to Find It;" March, "School Hygiene: Medical Inspection;" April, "Conservation of Vision: Prevention of Blindness;" May, "Infant Mortality: Don't Kill Your Baby," and June, "Food Sanitation: Needless Summer Dangers."

WISCONSIN

Work Starts on County Asylum.—Work was started September 11 on the new Shawano County insane asylum, Shawano. The building will be completed within a year.

Personal.—Dr. Robert A. Kitto, Racine, was seriously injured by being run down by an automobile, August 30.——Dr. Arthur H. Sanford, professor of physiology in Marquette University, Milwaukee, has resigned to take charge of the laboratory of the Drs. Mayo, Rochester, Minn.——Dr. Willard A. Pease, Rio, who was operated on recently for appendicitis, is reported to be securely convalescent.

GENERAL NEWS

Southwestern Physicians to Meet.—The Southwestern Medical Association, which includes the states of Missouri, Kansas, Oklahoma, Arkansas and Texas, will hold its annual meeting in Oklahoma City, October 10 to 12.

Annual Meeting of Missouri Valley Medical Association.—At the annual meeting of the Missouri Valley Medical Association held in Omaha, September 7 and 8, the following officers were elected: president, Dr. John M. Bell, St. Joseph; vice-presidents, Drs. Arthur C. Stokes, Omaha, and Dr. S. Grover Burnett, Kansas City; treasurer, Dr. Oliver C. Gebhart, St. Joseph; secretary, Dr. Charles Wood Fassett, St. Joseph. Colfax, Ia., was selected as the next meeting place.

Medico-Actuarial Investigation.—The medico-actuarial investigation which is now being made under the auspices of the Actuarial Society of America is a most important one. The experience of companies from 1885 to 1908 is being tabulated. The scope of t[illegible]uded a study of sixty-eight groups of [illegible] hazards and seventy-six of medical impairments. The figures are being tabulated in order to provide an accurate standard of heights and weights, and to determine the influence of build and occupation on longevity.

Cumberland Valley Physicians' Meeting.—At the ninth annual meeting of the Cumberland Valley Medical Association, held at Mount Holly Inn, near Carlisle, Pa., August 31, the following officers were elected: president, Dr. W. Frank Skinner, Chambersburg; vice-presidents, Drs. John C. Gilland, Greencastle; Luther H. Keller, Hagerstown, and David W. Van Camp, Plainfield; secretary, Dr. John J. Coffman, Scotland (reelected for the tenth time); assistant secretaries, Drs. Leslie M. Kauffmann, Kauffmann, Pa.; John R. Laughlin, Hagerstown, Md., and Edward Roberts Plank, Carlisle, Pa., and treasurer, Dr. R. P. Koons.

Societies to Meet.—Among the society meetings that are to occur in September are the following:

Amer. Acad. of Ophthal. and Oto-Laryngol., Indianapolis, Sept. 25-27.
Amer. Assn. of Obstet. and Gynecol., Louisville, Ky., Sept. 26-28.
American Roentgen Ray Society, Richmond, Va., Sept. 20-23.
American Urological Association, Chicago, Sept. 26-27.
Assn. of Military Surgeons of United States, Milwaukee, Sept. 26-29.
Indiana State Medical Association, Indianapolis, Sept. 28-29.
Michigan State Medical Society, Detroit, Sept. 27-28.
Pennsylvania State Medical Society, Harrisburg, Sept. 25-28.
W. Va. State Med. Assn., White Sulphur Springs, Sept. 20-22.

Electrotherapeutic Association Meeting.—The twenty-first annual meeting of the American Electrotherapeutic Association was held in the College of Physicians, Philadelphia, September 5-7. The following officers were elected: president, Dr. William D. McFee, Haverhill, Mass.; vice-presidents, Drs. F. Howard Humphris, London, Eng., and George E. Pfahler, Philadelphia; treasurer, Dr. Emil Heuel, New York City; secretary, Dr. J. Willard Travell, New York City; registrar, Dr. Frederick M. Law, New York City, and trustees, Drs. Frederick deKraft, Haverhill, Mass., and Francis B. Bishop, Washington. The next meeting will be held in Baltimore in September, 1912.

CANADA

Academy Moves.—The Toronto Academy of Medicine has moved into large and commodious quarters in Queen's Park.

"King Cook" is Dead.—James Cook, who was known as "King Cook" to thousands of graduates of the medical department of McGill University, Montreal, and who for forty years was janitor in that institution, died August 15.

Hospital Notes.—The pathologic wing of the new Toronto General Hospital is almost ready for occupancy.——The new hospital for the insane at Coquitam, B. C., is progressing rapidly toward completion.——St. Mary's Hospital, New Westminster, B. C., is to be enlarged at an expense of $20,000.

Society News.—The Maritime Medical Association has voted itself out of existence, the step being taken in the interests of the Canadian Medical Association.——The British Columbia Medical Association held its annual meeting at Vancouver, August 30 and 31.——The first annual meeting of the Canadian Public Health Association will be held in Montreal, November 21 to 23.

Tuberculosis Sanatorium Open.—A new sanatorium for consumptives at Ste. Agathe des Monts, was recently opened. The institution is situated in the Laurentian mountains and is a little more than 100 miles from Montreal. The building is modern, the equipment admirable and the institute has at the present time a capacity of fifty beds. It has been erected by and is maintained under the auspices of the Laurentian Society.

Montreal Death Rate.—The death-rate in Montreal in 1910 was 22.40 per 1,000 as compared with 22.03 for 1909. There were 10,221 deaths during the year, 16,616 births and 4,386 marriages. In 1907 there were 919 deaths from tuberculosis; in 1908, 1,000; in 1909, 1,114; in 1910, 1,336, the increase being probably due to more complete returns. During 1910 8,749 cases of communicable diseases were reported.

Personal.—Prof. Dr. J. George Adami, Montreal, has started for the tuberculosis conference in Rome.——Dr. William Warwick has resigned as pathologist at the General Hospital, St. John, N. B.——Drs. Alexander S. Monro, Vancouver, John N. Elliott Brown, Toronto, and Dr. Duncan Graham, Toronto, have returned from Europe.——Drs. Charles O'Reilly, Toronto, and John H. Leeming, Winnipeg, have started for Europe.——Dr. Bruce of London, England, has been appointed superintendent of the London (Ont.) Tuberculosis Hospital.——Dr. J. Wilfrid Good, Winnipeg, was operated on recently at Rochester, Minn.——Dr. Duncan Graham has been appointed lecturer on bacteriology at Toronto University.

Tuberculosis Sanatoriums in Canada.—Dr. Charles D. Parfitt, Gravenhurst, Ont., reports in the *Dominion Medical Monthly* for August that there are now more than twenty tuberculosis sanatoriums in Canada. The movement was initiated in 1897. Twelve of these sanatoriums are in Ontario with a capacity for 547 beds, and treated during the last year 1,421 patients. It is estimated that there are at present in Ontario 10,000 cases of active tuberculosis and that 171,000 of those now living in the province will die from tuberculosis at the present rate. The death-rate from tuberculosis has diminished in Ontario and this, Dr. Parfitt believes, demonstrates and shows the value of sanatoriums. In 1897, when the sanatorium movement began the death-rate was 150 per 100,000, while in 1908 the rate from this cause was reduced to 112 per 100,000. The percentage of death from tuberculosis in 1908 was 7.7, which compares favorably with the rate of 11.0 which was reported in 1901.

LONDON LETTER

(From Our Regular Correspondent)

London, Sept. 2, 1911.

Annual Exhibition at the Royal College of Surgeons: The Prehistoric Races of Europe

Among the specimens added to the Museum of the Royal College of Surgeons, shown at the annual exhibition which has recently been opened, is one of unusual interest to those who are investigating prehistoric races. Hitherto no remains of a Bushman-like race have been found in Spain or France. However, during last winter Col. Willoughby Verner discovered in an unexplored cave in Spain fragments of the skeleton of a man covered by stalagmite and fossilized, of pigmy stature (4 feet 10 inches) and showing decided affinities to the Bushman type. Colonel Verner presented these remains to the museum, where they may be seen side by side with nine skeletons of Bushmen excavated from old graves in the Kalahari Desert. Prehistoric research is showing how abiding some of the types of mankind are, but it will be a remarkable revelation if it shall be finally proved that in the almost extinct race of South-African Bushmen we have representatives of the natives of Spain at the close of the glacial epoch. The Bushmen, the most specialized and peculiar of the negroid races, show a curious mixture of the adult and juvenile characters in their skeletons.

The Incidence of Anthrax

In spite of every precaution which science can suggest and a benevolent government enforce cases of anthrax continue to occur among workers in skins and hides. An important report on the incidence of anthrax and the means of preventing the disease has been presented to the Company of Leathersellers by Dr. Constant Ponder, bacteriologic assistant at the Leathersellers Company's Technical College. He finds that about 40 per cent. of all cases of anthrax that occur are due to handling Chinese or East Indian goods. Cutaneous infection is the most common, pustules on the head or neck occurring in 82 per cent. of the cases. No case of pulmonary anthrax, such as occurs among the Bradford woolworkers, has been observed in the workers in skins and hides and only two cases of intestinal anthrax in the last seven years. The point of greatest importance made by Dr. Ponder is that the anthrax spore is most likely to be found in discharges dried on fur or in blood spilled when the animal was flayed, and dried on the fur, and at the cut end of cutaneous capillaries. Hence the problem is how to destroy the spores when protected by a thin layer of blood, mucus, or fecal material without damaging the hides. Having studied the methods suggested from time to time at home and abroad Dr. Ponder recommends one based on the fact that no case of anthrax has ever been traced to wet, salted hides. He therefore recommends that all hides and skins should be imported in this state.

The same result can be achieved, adopting the method suggested by Mr. Seymour Jones, chairman of the International Commission for the Preservation, Cure and Disinfection of Hides and Skins. By this method the hides are practically converted into the wet salted state. They are soaked for twenty-four hours in a solution containing 1 per cent. formic acid and 0.02 per cent of mercuric chlorid and then transferred to the ordinary brine bath. This method destroys infection and does not interfere with the subsequent transformation of hide into leather.

The Dangers of Flannelette

Scarcely a day passes without a record in the press of some sad fatality, of which a helpless child is generally the victim, due to clothing made of flannelette catching fire. And yet, in spite of the verdict of a special home office commission, which investigated the matter, and that of coroners and juries throughout the country, who unite in condemning this material (which becomes more and more dangerous each time it is washed) no steps have yet been taken to decrease the heavy annual death-roll from this cause. In a pamphlet with the above title, the National League for Physical Education and Improvement makes out a strong case for legislation, basing its facts on evidence taken from blue books, on statements made by coroners, and on an independent investigation, recently carried on at the league's instigation by the *Lancet*. Deaths from burning, especially among children, are shown to be on the increase, and it is computed that of these deaths no less than a thousand a year in the United Kingdom may be ascribed to the fact of the victim having been clothed in ordinary flannelette. Nor is this surprising, when one realizes that if a child's flannelette garment becomes ignited that child is doomed if no person arrives within about three seconds to save it.

Some manufacturers appear to be alive to the dangerous nature of flannelette and are trying to remedy matters by making it with a short, close nap. But even this is not, according to the *Lancet's* tests, as trustworthy in regard to safety from fire as flannelette which has been treated by a lasting, chemical, fire-proofing process. Such flannelettes have been on the market for some time now. The danger to the public, however, lies in the fact, as proved by the *Lancet*, that not only is flannelette still sold at large with no pretensions to being non-inflammable, but flannelette is also sold which wrongly claims to be non-inflammable.

Here then, as a first step, is where legislation is urgently needed. It should be made penal, as recommended by the home office commission and the Lancet, to describe as uninflammable materials which will not stand certain prescribed tests for inflammability.

Tuberculosis Among Railway Clerks

An investigation of the prevalence of consumption among railway clerks has just been completed by the Railway Clerks' Association. It is found that 42 per cent. of the deaths among these clerks are due to the disease as compared with 25.8 in the general population. The officials of the association express the view that consumption is an occupational disease, which is encouraged by the unhealthy surroundings in which many railway clerks are obliged to work and that much could be done if the standard of sanitation and ventilation imposed under the factory acts were made obligatory in railway booking and other offices. A bill has been prepared with this object and will be presented to Parliament in due course. One of the large railway companies, the Midland, has decided to give immediate effect to some of the recommendations for checking the growth of the disease and have announced that when clerks are attacked they will allow six months leave with full pay.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Aug. 25, 1911.

Death of Professor Dieulafoy

Dr. Georges Dieulafoy, former professor of clinical medicine at the Faculté de médecine de Paris, has just died rather suddenly, aged 62. He was born in Toulouse and first studied medicine at the Ecole de Médecine of that city. Then he came to Paris, where he became the favorite pupil of the celebrated clinician, Trousseau. He received his doctor's degree in 1869, and was appointed *agrégé* professor in 1875. Twelve years later he obtained the chair of internal pathology at the Faculté de médecine de Paris. He was at first physician at the Necker hospital, and in 1869 went to the Hôtel-Dieu as professor of clinical medicine where he succeeded his master, Trousseau. In 1891 he was elected member of the Académie de médecine and was later chosen president of the academy. He had retired from his professorship two years ago.

The first work by which he became well known was his treatise on the aspiration of morbid exudates, published in 1873. Dieulafoy's aspirator has for a long time been employed for the evacuation of pleuritic fluids. Dieulafoy also drew the attention of physicians to the signs of obscure diseases and in particular to those of the insidious condition which he called *petit brightisme*. In later years he was occupied, with an evident predilection, with medicochirurgical questions, such as the treatment of appendicitis, early operations in ulcerating gastritis and diseases of the liver, kidney, etc. Dieulafoy's principal claim to distinction rests on his "Manual of Internal Pathology" from which many generations of students have been taught and which has gone through sixteen successive editions since 1880. He also issued the "Clinique médicale de l'Hôtel-Dieu" in six volumes.

Dieulafoy was not a laboratory man, but his remarkable facility for assimilation permitted him to put himself rapidly in touch with laboratory discoveries and to use them in his teaching. What especially contributed to his success as an instructor, however, was his great facility of language—his oratorical ability. It might even be said that his eloquence carried him a little too far sometimes. He was a little too fond of formulas. Thus about twelve years ago he made a sensational communication to the Académie de médecine which was summed up in the striking epigram that "no one ought to die of appendicitis," which is as much as to say that appendicitis should be operated on immediately in every case. Surgeons naturally hastened to follow his advice to such a degree that in 1906 Dieulafoy again mounted the tribune of the Académie de médecine, this time to reproach surgeons with operating too much. Many people merely affected with mucomembranous typhlocolitis, he said, were unnecessarily operated on for a non-existent appendicitis.

The Twenty-First Congress of Alienists and Neurologists

The twenty-first Congrès des médecins aliénistes et neurologistes de France et des pays de langue française was held August 1 to 6, at Amiens. It was not so successful as in previous years, owing perhaps to a defect in organization. The sessions of the congress were scattered in a way, being held now at Amiens, now at Boulogne-sur-Mer and now at the asylum of Prémonté, the members of the congress having to go to these various places at their own expense, which more than doubled the usual cost of 20 francs ($4). Another more important cause of unsuccess to which Dr. Deny, physician of the Salpêtrière and president of the congress, called attention in his opening address, consists in a certain coolness between the neurologists and alienists. This is due perhaps to the fact that psychoneuroses form a kind of debatable ground. Three interesting questions were considered.

VALUE OF LEGAL EVIDENCE GIVEN BY PERSONS OF UNSOUND MIND

Dr. R. Lalanne, head physician at the insane asylum of Maréville, Nancy, showed how the ordinary variation of evidence emphasized by recent researches in experimental pathology, the disturbances of perception (illusions, sensorial disturbances of the aged, etc.) gradually lead onto pathologic ground—to the evidence of persons of unsound mind whose mental disturbance is not suspected by the public or by the judges. The value of the evidence of these unsuspected insane persons is essentially variable. Lalanne, therefore, insisted particularly on the utility of having the judges rely on the assistance of a psychiatrist whenever they suspected a morbid mental condition in the witness. The expert should not pass on the evidence itself. He should confine himself to declaring whether the condition of the witness' mind is or is not such as to cast doubt on his evidence.

On the motion of Dr. Rémond of Toulouse, the congress passed two resolutions, one declaring that the evidence of any person who is or has been mentally unsound should be legally declared under suspicion, and the other emphasizing the value for judges of a course including medicolegal psychiatry.

Professor Ladame of Geneva drew attention to the severity of the law against perjured testimony. Since there are undoubtedly many psychopathic persons among the public at large, he offered a resolution which was passed to the effect that before conviction for perjury the court should have the mental condition of the perjured witness examined. The congress also passed a resolution offered by Dr. Ley of Brussels demanding that the methods of psychologic experiment should be used to test the evidence given by the insane.

TUMORS OF THE PITUITARY

Dr. Courtellemont of the Ecole d'Amiens divides the symptoms which indicate tumors of the hypophysis into results of the mechanical disturbances (signs of cerebral compression, properly speaking, headache, vomiting, vertigo, nerve compression and especially ocular troubles, etc.), and dystrophic conditions. As for the latter the present tendency is to attribute acromegaly and gigantism to the hyperfunction of the gland, and the adipose-genital syndrome to the hypofunction. There would thus be opposition between the two syndromes of hypofunction and hyperfunction. From the therapeutic point of view it seems certain that we are no longer helpless with regard to pituitary tumors. Even though opotherapy appears to be only a symptomatic treatment, radiotherapy has given very appreciable functional and physical results. In particular it diminishes the phenomenon of encephalic compression and ameliorates visual troubles. Partial hypophysectomy has given very good results in the hands of von Eiselsberg, Hochenegg, and others. It alone of all the therapeutic methods seems to have succeeded in causing the regression of acromegalic deformities. Nevertheless, in view of the still very formidable seriousness of the operation, Dr. Courtellemont thinks that it should be reserved for cases which resist opotherapy and radiotherapy.

Dr. Paul Sainton of Paris emphasized the special characteristics of glycosuria in cases of tumors of the hypophysis. The proportion of sugar is much higher than in other glycosurias of nervous origin. Moreover the glycosuria is accompanied by all the symptoms of real diabetes, polyuria, polypnagia, polydypsia, so that the expression, "hypophyseal diabetes" is entirely justified. These facts should be compared with the cases of diabetes in that other syndrome of hypofunction, namely, Basedow's disease (hyperthyroidism).

THE VARIOUS CLASSES OF PSYCHOPATHIC PAINS

The most important part of the paper presented by Dr. G. Maillard, assistant physician at the Salpêtrière, is the therapeutic portion. Should operation be performed for psychopathic pains? A distinction should be made among these. If there is an important lesion which in itself is an operative indication, evidently operation should be done and it may be hoped that the pain will disappear or at least a remission or attenuation be obtained according as the psychic or organic factor predominates. In cases in which there is no organic lesion apparently capable of producing psychopathic pains no operation should be done. Operation, real or pretended, would serve no purpose and in pains of paranoiac origin such operation would only furnish new ground for delusion. But between these two extreme cases there are many intermediary cases in which the proper course to follow is open to discussion. These are the cases in which the psychopathic pains seem connected with a lesion which in itself does not absolutely require operation but in which an operation would be justified as thereby the pains might be made to disappear. These embarassing cases are found, for example, in displacements of organs, movable kidney, uterine prolapses, etc. In such cases to try to do the best for the psychic condition and for the lesion is often very difficult. If the pain is a manifestation of a hysterical organic association the best chances of improving the condition of the patient or of effecting a cure are to be found in appropriate surgical measures together with psychotherapeutic measures.

Dr. Picqué of Paris emphasized the fact that a cerebral condition of the patient may constitute a contra-indication against an operation which would be indicated in patients whose mental condition is normal. Of course, in urgent cases operation should be done whatever the mental condition of the patient. But in elective surgery (for example, early operation on uterine fibromas), the mental condition should be reckoned with. Picqué believes that before any operation the mental condition of the patient should be examined as regularly as the urine.

PAINS AND PSYCHIC PHENOMENA

Apart from the three main questions of the day discussed in the congress an interesting paper was read by Dr. André Léri, *agrégé* professor at the Faculté de médecine de Paris, tending to show that contrary to the general opinion, pain is not an intellectual or even a cerebral phenomenon. Pain exists in the absence of brain. Léri had an opportunity to examine repeatedly an anencephalus which lived three days. The child cried and struggled when it was pinched at the level of the limbs or of the face. It showed evident signs of pain. At the autopsy not only was no brain discovered, but there was not even a trace of protuberance. There was indeed a trigeminal nerve and Gasserian ganglion on each side, but from the ganglion the efferent nerve lost itself in the fibrous tissue on the border of the temporal bone. The trigeminal is considered the only sensory nerve of the face and the infant felt it when its face was irritated. Thus painful sensation seems to exist not only independent of the brain but even independent of any nerve center.

Death of Prof. G. Julliard

Dr. G. Julliard, former professor of clinical medicine at the Faculté de médecine of Geneva and formerly chief surgeon of the cantonal hospital of that city, has just died. He studied medicine in Paris from 1857 to 1865. Dr. Julliard took an important part in the organization of medical instruction which was inaugurated at the Université de Genève in 1876. He had the honor of installing open-air pavilions at the cantonal hospital which before the antiseptic period contributed to combat effectively the hospital gangrene which raged so cruelly in Geneva during the quartering of the French troops in 1871. He also carried on an earnest propaganda for the substitution of ether for chloroform in surgical anesthesia. Dr. Julliard was foreign correspondent of the Académie de médecine de Paris.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Aug. 25, 1911

Personal

Prof. A. Seligmüller, the neurologist of Halle, celebrated the semicentennial of his doctorate August 22.

The renowned Jena obstetrician and gynecologist, Prof. Bernhard Sigmund Schultze, celebrated the sixtieth year jubilee of his doctorate August 27.

The noted Bern surgeon, Professor Kocher, celebrated his seventieth birthday on August 25.

An Address of the Kaiser

On the occasion of his stay in Cassel, our Kaiser dedicated a new banner (in place of the one given by his father) at the gymnasium of that place, at which, as is well known, he received his schooling. In connection with it he delivered an address to the pupils of the highest classes, in which among other things he emphasized the importance of liberal studies. In the study of antiquity the emphasis should be placed not on the peculiarities of political life, which were entirely different from those of the present day, but on the harmony in art and philosophy which was peculiar to the Grecian people above all others and is especially lacking in our day; at the same time, study of the history of the fatherland should not be neglected. These statements are especially remarkable for the reason that they might suggest a retraction on the part of the Kaiser of the excessive estimate of physical science, which he gave in a speech a few years ago. At that time his words formed an introduction to the preference for scientific schools in Germany and further for the admission of graduates of these schools to the study of medicine and law. Probably now greater weight will be laid henceforth on the classical studies again and consequently the danger of the regular classic course becoming more and more neglected will be averted. In addition the Kaiser also in this address again emphasized the injuriousness of the misuse of alcohol, especially for college students. On this occasion he praised the custom of excluding the use of alcohol adopted by the college men in America; of whose ability we have often had occasion to be convinced, and he advised his audience to strengthen the body through sport, rather than to establish a record in the consumption of alcoholic drinks.

Shorter Hours in the Prussian Higher Institutions of Learning

The so-called short period of forty minutes already adopted in most of the Berlin higher institutions of learning is to be extended to all the similar institutions of Prussia according to a decision of the Prussian minister of education. In the edict the minister makes it the duty of the directors to exercise careful supervision, to see that no increase of work at home results from the shortening of the time of instruction in school, so that especially the free afternoons shall be devoted to physical recreation in the open air and to spontaneous intellectual work, if necessary by calling on the parents for aid. At the same time, the minister cautions that the pupil must not be under any compulsion to take part in the optional courses in the school.

Aid Bureau for Persons Discharged from Insane Asylums

Persons who have been discharged from an insane asylum and have now again to take up the battle of life as well as mentally abnormal people in general but who are not ill enough to need institutional care, have always caused great and often insurmountable difficulty to public charity. Already ten years ago the idea was advanced in Berlin of providing a special kind of care for this class of persons needing aid. Now a bureau for the care of discharged lunatics is being established on the basis of a program put forward by Privy Counsellor Moeli, chief of the Herzberg Asylum. The fundamental idea of this arrangement is that these persons need aid directed by a psychiatrist. There are four functions for the bureau: 1. Immediately after discharge, of which as far as possible the bureau must be previously notified, a suitable lodging must be provided, as far as possible in a family. Subsequently this lodging is to be permanently supervised. 2. Employment fitting the individual capacity and conditions of the patient is to be provided, and the bureau is to secure an appropriate place to work, in which the one receiving care shall be employed, at first necessarily at small wages and gradually providing for an improvement of the conditions of labor. 3. Also the conduct of the patient must be constantly superintended, and in the case of those previously addicted to alcohol, they are to be induced to join temperance societies, and injurious associations are to be prevented if necessary by removal to another environment. 4. To aid the ward in all business relations of daily life.

It has been determined to adopt a mixed form of care, similar to that which has already been adopted in the infant welfare stations. The station will be placed under the supervision of a salaried physician. The business management is to be looked after by a municipal official. The soul of the special care is a salaried nurse experienced in the treatment of those mentally afflicted. She will be aided by a number of unsalaried assistants.

Protest of Physicians at Königsberg Against Pollution of Water

In Königsberg the River Pregel which flows through the city has for many years given off a quite intolerable odor. This nuisance, of which much complaint has been made in the course of time, has not been removed, in spite of all the efforts of the city authorities. The odor has become even stronger in the last year. The water of the Pregel is of a dark color and with a west wind exhales a pestilential smell which extends far into the suburbs. Last Saturday the local physicians determined to present a remonstrance to all of the present authorities, declaring that it is held to be an elementary duty of all of the officials who have to do with the matter to leave nothing untried in order to remove this disgusting nuisance from the city. The president of the Königsberg medical association (*Aerzteverein*) was commissioned to forward a copy of this protest to the governor of the province, to the national legislature, the mayor and the city council.

The Movement of the Population in Germany in 1909

According to the official statistics just published, there were in the German empire in 1909, 494,127 marriages; this is 6,493 or 1.3 per cent. less than the previous year. Also the number of births has diminished. There were in 1909, 2,038,357 children born; in 1908, 2,076,660, so that the number of births has been reduced by 1.8 per cent. The number of deaths has fallen still more, as in 1909 there were 1,154,296 deaths as against 1,197,098 in the previous year, a reduction of 3.6 per cent. In spite of the considerable increase in the German population, the number of deaths is the smallest that has been recorded since the foundation of the empire. For every 1,000 inhabitants there were in 1909 15.48 marriages, 31.91 births and 18.07 deaths; in the previous year these figures were 15.88, 32.97 and 19.01. The natural increase of the German people or the excess of births over deaths, was 884,061, or 13.84 per thousand of the population. The age of those marrying was, among the men, under 25 in 30 per cent. of the cases and in 71.5 per cent. under 30 years, and among the women, in 58.2 per cent. under 25 years. Of the 2,038,357 births in the year 1909, 97.05 per cent. of the children were born living and 2.95 per cent. were still-born; 12.8 per 1,000 of the births were plural births;of these 25,893 were twins, 261 triplets and three quadruplets. In all 52,581 children were born in plural births. Of the 1,154,296 deaths in the year 1909, 60,079 were born dead and 335,436 were children under one year. For every 100 born there were seventeen deaths in the first year of life. This indicates a reduction of the infant mortality over that of the previous year, but it is still a very considerable figure in comparison with other civilized countries.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

PROGRESS OF PHARMACOPEIA REVISION

I. THE PHYSICIAN AND THE PHARMACOPEIA; GENERAL PRINCIPLES

The Executive Committee of Revision, after fifteen months of labor, has made public its first report[1]; this deals with a subject of decided interest to physicians, the scope of the Pharmacopeia.

In order to discuss the Pharmacopeia from any standpoint it is essential to keep clearly in mind what the Pharmacopeia is or purports to be. It is sometimes stated that the Pharmacopeia is now a "law book," but it is this only incidentally. As pointed out in recent court decisions, it was simply adopted as a legal standard for the articles which its owners care to include in it; there is therefore no reason for the latter to consider this aspect of the question further than it suits their purposes to do so.

The Pharmacopeia of the United States originated by physicians is now the exclusive property of the medical and pharmaceutical professions—professions which are assumed to be working together for the good of the sick and the protection of the well, and supposed to discountenance any practices incompatible with these aims, and to warn their clientele against practices or drugs which will be either harmful or useless. The specious argument that the public "calls" for worthless things and that it is legitimate to supply this want was long ago repudiated by the medical profession, if indeed it was ever recognized, as it also is by most pharmacists.

---

[1] American Druggist, Aug. 28, 1911, p. 23.

These several considerations, if adopted, would naturally narrow the scope of the Pharmacopeia and find their logical expression in the "guiding principle" adopted by the present Committee of Revision, namely, that admission to, or retention in the Pharmacopeia should be determined by "therapeutic usefulness or pharmaceutical necessity."

It is by this guiding principle that the work of the Committee of Revision, as indicated by the present report on the scope, is to be judged. This brings us at once to the question as to how the committee has acquitted itself from the standpoint of the medical profession. We presume physicians have the right to ask this question, since the book was originated by physicians and because more than 60 per cent. of the organizations entitled to take part in the revision are medical organizations and by a further fact that slightly more than 50 per cent. of the organizations actually represented at the last Pharmacopeial Convention were medical organizations.

No committee of revision in recent years has had such excellent opportunities to learn the wishes of physicians as regards the scope of the Pharmacopeia as has the present one. The subject was under active discussion at medical meetings for several years before the Committee of Revision was selected. Various medical societies, including the American Medical Association and most of its sections, had special committees on the subject. Some of the societies arranged for a system of balloting by all their members. The Committee on the U. S. Pharmacopeia of the Association secured a vote on all the articles in the United States Pharmacopeia from the teachers of materia medica and therapeutics in the medical colleges of the United States. This material was carefully tabulated and printed and was freely accessible to the Committee of Revision. It may be said that there was an almost complete unanimity of opinion of the large number of physicians taking part in this work as to what the Pharmacopeia should be: it was that it should be a book which should reflect the best drug therapeutics of the United States and further that it should contain only remedies of recognized and established value so that the recognition of a drug by the Pharmacopeia would be, as it is generally taken to be, an assurance that the best medical thought at present holds it to be of established value. No other conclusion could possibly be drawn from this large amount of evidence; those who held any other view of the scope of the Pharmacopeia were in an extremely small minority.

Viewed from this standpoint the present report of the Committee of Revision is disappointing.

II. PROPOSED ADDITIONS AND DELETIONS

The proposed admissions[2] to the U. S. P. IX may be considered first, for it is by admissions that most physicians will judge the ability of the Pharmacopeia to adapt itself to the needs of modern medicine. To the extent that a pharmacopeia, for any reason whatever, is unable to include drugs which are in constant use by large numbers of well-informed practitioners, to that extent it can not expect to receive the cordial support of the profession. It is proposed to admit thirty-nine new drugs in the next revision. While it would be of interest to know by what process of inquiry the revision committee was led to think that there is a widespread, intelli-

gent demand for some of the preparations it is proposed to admit (aspidospermin, apiol, calcium glycerophosphate, for example) the failure to admit or make any reference to a number of specific recommendations of large and important bodies of physicians must cause surprise.

As has been pointed out, several sections of the American Medical Association, after long and careful study, made recommendations as to a number of admissions; surely no one would question that the members of these sections are well qualified to state what is needed by the practitioners of this country.

These recommendations have thus far received favorable consideration to but a very limited extent. With the exception of the report of the Section on Practice of Medicine (five of the six recommendations of which were accepted) there is nothing to indicate that these valuable reports were considered. Thus none of the recommendations of the Section on Obstetrics and Gynecology was adopted, but one of those of the Section on Ophthalmology, and four of those of the Section on Stomatology. It is true that some of the recommendations were not very definite, but they represent pharmaceutical problems encountered by physicians, problems which it would be natural to expect the Committee of Revision to solve. No doubt the latter could solve them if it was given the necessary means and assistance to carry on research work, especially if the former Committee of Revision had been at work on them in the long interval since the last revision.

Thus while the Committee of Revision should not be blamed, especially since most of the members serve with practically no direct remuneration, yet the important fact remains that when physicians meet pharmaceutical problems they are, apparently, unable to secure help from the logical source, namely, the Pharmacopeia. It is to be hoped that some of these problems are not mentioned in the present report because they are receiving further consideration.

It is proposed to delete 154 articles. With the thirty-nine additions this will still leave approximately 850 articles in the U. S. Pharmacopeia, a number which seems out of all proportion to the needs of modern medicine, especially when it is noted that about 20 per cent. of these are peculiar to the Pharmacopeia of the United States.

It is not likely that well informed physicians will miss many of the 154 articles it is proposed to delete, and it is a question if there is not an almost equal number retained which might have been deleted with as much or more justification; this was the opinion of a majority of the teachers of materia medica and therapeutics of the medical colleges who voted on this subject (and their collective wisdom is perhaps equal to the wisdom of the fifteen members of the Executive Committee of Revision with its one practicing physician).

As a matter of fact it is proposed to retain a number of peculiarly objectionable drugs. These include several plant drugs long since recognized as devoid of value or as having but a very secondary value, the main use of which is to deceive the people in one way or another, either as ingredients of "patent medicines" or of equally undesirable "ethical proprietaries."

The list includes such little used (by physicians) drugs as cinchonin, eupatorium, matricaria, rhus glabra, sabal, salvia, etc. Some of these are undoubtedly much "called for" by the laity, i. e., by the "patent-medicine" people; others are prominent in the names of certain "ethical proprietary" mixtures, and serve to overshadow the really important constituents; there is probably a large "sale" for them—but these are not tests of "therapeutic value." The vigor with which some of these drugs are repudiated by the medical profession is shown by the fact that they were recommended for deletion by the Section on Practice of Medicine, and by the majority of the teachers of materia medica and therapeutics and by certain medical societies; moreover they are comparatively little used on prescription.

It is also interesting to note that the Section on Obstetrics and Gynecology, the members of which are preeminently the best qualified to judge, voted to delete gossypii cortex and glyceritum hydrastis, which the Committee of Revision propose to retain, and that they voted to retain cerii oxalas, which it is proposed to delete; that the Section on Dermatology stated that the only plasters of value to dermatologists are the emplastrum plumbi and emplastrum hydrargyri; the revision committee proposes to delete the latter and to retain some used chiefly by the laity.

Previous revision committees have excused the shortcomings of the Pharmacopeia on the ground that so few physicians, and those not always representative, took an interest in the work; the present committee cannot make this excuse, for thoroughly representative bodies of active practitioners have supplied much more information than the committee seems to have been able to assimilate. Interests other than those of modern progressive medicine seem still to preponderate in pharmacopeial management.

While the report is disappointing in many ways, yet the encouraging feature is that the tide seems to have turned, and that the degeneration which Dr. Jacobi said was noticeable in recent revisions seems to have been checked, for a Pharmacopeia constructed on the lines which are foreshadowed by the first report of the Executive Committee of Revision is certainly a decided improvement over its immediate predecessor, and should encourage physicians to renewed activity and interest.

THE CHARGE AGAINST DR. WILEY

Extracts from the Testimony Given Before the Congressional Committee

(Continued from page 916)

THE INDIANA CASE

[A brief statement of the facts regarding what is known as the Indiana case appears editorially in this issue. It is there shown how the power of the federal government was used to assist Curtice Bros. and Williams Bros., in their attempt to have the pure food law of the state of Indiana declared unconstitutional. The matter that follows is taken from part of the testimony given before the Congressional Committee regarding the case. We first quote that part of the testimony of President Remsen, chairman of the referee board, that refers to the Indiana case.]

[President Remsen's Testimony]

Mr. Floyd. I want to ask you some other questions in connection with the benzoate of soda inquiry, and will ask that if you cannot give the information about the matter now, you will supply it to us later. I will ask you to state, if you know, whether or not Curtice Bros., of New York, and Williams Bros., of Detroit, Mich., are among the leading manufacturers of benzoate of soda in the United States?

Dr. Remsen. I do not know that I have ever heard that they were manufacturers of benzoate of soda.

Mr. French. You do not mean manufacturers of benzoate of soda?

Mr. Floyd. No, sir; I mean of the products in which benzoate of soda is used.

Dr. Remsen. All that I know about it is from signs that I have seen along the railroads.

Mr. Floyd. They use it, do they not? Are they not the principal users?

Dr. Remsen. I do not know.

Mr. Floyd. But you know it is used in the commodities you saw advertised by them?

Dr. Remsen. Yes, sir.

Mr. Floyd. They were products in which benzoate of soda is used, were they not?

Dr. Remsen. Yes, sir; in some of them it is used.

Mr. Floyd. I will ask you to state whether or not you were called on to give testimony against the State of Indiana in a suit against that state brought by Curtice Bros., of New York, and Williams Bros., of Detroit, Mich., in which case the pure-food law of the State of Indiana was involved, or, rather, a violation of it was involved.

Dr. Remsen. I would like to raise one question. I am not sure that the products of Williams Bros. and Curtice Bros. were involved, but there is a suit still pending, and I was called to give testimony in that suit.

Mr. Floyd. I will ask if you were called on to give testimony in a suit, in the State of Indiana, in which the enforcement of the pure-food law of the State of Indiana was involved?

Dr. Remsen. I was.

Mr. Floyd. Did you appear as a witness for or against the State in that suit?

Dr. Remsen. So far as my state of mind was concerned, I appeared for neither side. I simply wanted to state the facts as I knew them.

Mr. Floyd. At whose instance were you called?

Dr. Remsen. The first person who called on me was someone representing, I think, Curtice Bros. I told him I would not appear in the suit; that I did not care to get involved in it. He said that our report was involved in the suit; that our work was involved, and that it was due to the work which we had done to make certain statements, or to answer certain questions in regard to it. I then saw the Secretary of Agriculture, and asked whether he thought it was proper for me to give such testimony. He said that he thought it proper, and advised me to give it.

Mr. Floyd. Was that in relation to benzoate of soda or saccharin?

Dr. Remsen. Benzoate of soda.

Mr. Floyd. And your testimony was in relation to benzoate of soda?

Dr. Remsen. Yes, sir.

Mr. Floyd. And before going to give your testimony, you consulted with the Secretary of Agriculture, and he advised you that it was entirely proper for you to go and give the testimony?

Dr. Remsen. Yes, sir; because the report which we had given to the Secretary of Agriculture was at stake. We were told that they were going to attack this report, and that that would be in one sense the point of attack. They put it to us this way: That those who were responsible for the report ought at least to make some statement in regard to the character of it; that they could not put our report in as evidence, I believe, and they wanted testimony concerning the report, because the report itself could not be put in the record. That is all I know about it.

THE ATTITUDE OF THE SECRETARY OF AGRICULTURE

[The attitude of the Secretary of Agriculture in this case was made evident. From his standpoint, the government was pro-benzoate and, as such, must champion the cause of those manufacturers who use this chemical preservative.]

The Chairman. When you referred the matter to the Secretary of Agriculture for his advice as to whether you should testify or not, if he had advised you not to testify would you have given your testimony?

Dr. Remsen. Well, of course, that is a hypothetical question. I don't think we should.

The Chairman. You don't think you should?

Dr. Remsen. No. We were anxious not to appear in the suit at all.

The Chairman. When Dr. Chittenden asked your advice and you advised him to go, if you had advised him not to go do you believe he would have gone?

Dr. Remsen. That would depend on the pressure brought to bear on him from better and higher sources. Possibly the Secretary of Agriculture might have advised him to go even if I had advised him not to go. I think he would have followed the advice of the Secretary.

The Chairman. You spoke about having an aversion to giving testimony, but that the aversion was overcome. Now I want to know what force it was that led you to overcome that aversion?

Dr. Remsen. The whole force was a feeling on our part that perhaps we could aid those who were engaged in trying the suit to get at the real facts in the case.

The Chairman. Did you consider the question as to whether it would be proper, being a member of the referee board, on that account, for you to give testimony?

. . . .

Dr. Remsen. The way it lies in my mind now is the way it lay in my mind at that time, I am sure. I could not see any objection to giving a deposition in regard to the character of our work and the general relation we held toward the work which had been done. We had no feeling, as I say, no desire whatever to support anyone or to undermine anyone.

The Chairman. But you understood, however, that the defendant in this case was the State of Indiana?

Dr. Remsen. Yes; I did get that into my head after awhile. It took some time to do so, I must say.

The Chairman. And that it was the contention of the authorities of the State of Indiana and of the state chemist that the use of benzoate acid as a preservative for food was harmful to the public health?

Dr. Remsen. Yes; I understood that.

The Chairman. And you understood also that the judicial department of the State of Indiana was attempting to exclude from sale in our state any foods that used benzoate of soda as a preservative?

Dr. Remsen. I do not know anything about the machinery and did not know exactly where the matter stood; but I knew the suit had been brought. Exactly how it was brought or why it was brought I did not know then and do not know now.

The Chairman. And you knew, too, that if you gave testimony, your testimony would be favorable to the use of benzoate of soda as a preservative of foods?

Dr. Remsen. I suppose I knew that, although that did not enter into my thoughts. I am perfectly sincere in saying that all I wanted to do was to help these gentlemen as far as I could in arriving at the facts.

The Chairman. And the result would naturally follow, that whatever prestige you had gained by the fact of being a member of the referee board would naturally be against the contention of the State of Indiana in their enforcement of what they considered to be the pure-food laws of our state.

Dr. Remsen. I suppose that passed through my mind, although I did not spend any time worrying about it, because that was not what I was asked to think about.

The Chairman. Now, then, did that particular phase of it bring to your mind this particular question of propriety that you had in mind which caused you to refer this matter to the Secretary of Agriculture for his advice?

Dr. Remsen. I don't think that phase of it did; no. It was a general question as to whether the members of the referee board who had been called on by the United States Government—I think I can say that—to pass on certain scientific questions and had handed a report to the Secretary of Agriculture—it did occur to me that there might be some impropriety in a member of that board appearing in any capacity as a witness if he could help it. We cannot always help it.

The Chairman. And the Secretary advised you that there would be no impropriety in so appearing?

Dr. Remsen. Yes, sir.

The Chairman. And did he say it was your duty to do it?

Dr. Remsen. I don't think he put it as strong as that: but I got about that impression from what he said. The point was, as I remember it in our conversation, he said: "Gentlemen, you have made a report which you have signed; that is your statement. Now, that is called in question and if you are asked to answer questions in regard to it, it seems to me entirely proper that you should answer those questions." That was the way the matter was presented to me and it seems now a reasonable way—

Mr. Higgins. .Were you under summons from the court?

Dr. Remsen. No; I never was.

THE ATTEMPT TO DEPRIVE INDIANA OF DR. WILEY'S TESTIMONY

[Knowing that the Secretary of Agriculture was wedded to the pro-benzoate side of the question, Solicitor McCabe tried his best to prevent Dr. Wiley, whose views against the use of sodium benzoate are well known, from going to Indianapolis to testify.]

[*Solicitor McCabe's Testimony*]

Mr. Floyd. Now, I will ask you to state if you know anything about the case that was pending in the State of Indiana between Williams Bros., of Michigan, and Curtice Bros., of Rochester, N. Y., against the State of Indiana, wherein the pure-food law of Indiana was involved?

Mr. McCabe. Yes, sir.

Mr. Floyd. Now, I will ask you to state if any of the employees of the Agricultural Department attended that trial and gave testimony on either side.

Mr. McCabe. I do not know as to whether or not they attended the trial—that is, as to whether or not they went out before the master. But I know that employees of the Department of Agriculture gave testimony in the case.

Mr. Floyd. You do not know whether they attended or not, though?

Mr. McCabe. No, sir.

Mr. Floyd. And you do not know, if they did attend, how their expenses were paid?

Mr. McCabe. No, sir; I do not.

The Chairman. Were you requested to give an official opinion by the authorities of the State of Indiana as to whether Dr. Wiley might be permitted to give his testimony in that case?

Mr. McCabe. No, I don't think so, Mr. Moss. I was requested either by Dr. Wiley or Dr. Bigelow to give an opinion as to whether or not their testimony could be compelled—their testimony as experts could be compelled.

The Chairman. What advice did you give Dr. Wiley on that?

Mr. McCabe. I gave him the advice that he could not be compelled to testify as an expert in that case.

The Chairman. What effect did that have on securing or depriving the State of Indiana of Dr. Wiley's testimony?

Mr. McCabe. None.

The Chairman. Dr. Wiley gave testimony in that case, did he not?

Mr. McCabe. Yes, sir.

The Chairman. Will you state to the committee how it came about that Dr. Wiley testified?

Mr. McCabe. I was absent from Washington at the time. I was on my leave. My understanding of the matter is that Dr. Wiley refused to testify on the strength of my opinion and that application was made by the attorney general of the State of Indiana to Mr. Justice Barnard, of the local Supreme Court of the District, and that Justice Barnard signed an order requiring Dr. Wiley and the other men to testify on the facts.

The Chairman. The request, then, came to the Department of Agriculture from the attorney general of the State of Indiana that Dr. Wiley be permitted to testify, did it not?

Mr. McCabe. Yes.

The Chairman. And the effect of your decision was that he should not testify.

Mr. McCabe. No, sir.

The Chairman. What was the effect of your decision?

Mr. McCabe. The effect of my decision was that he could not be compelled to testify in that case as a witness. I will say, frankly, that I did not want Dr. Wiley to testify in that case.

The Chairman. Did you advise him not to testify?

Mr. McCabe. No, sir.

The Chairman. Did the Secretary of Agriculture advise him not to testify?

Mr. McCabe. Not to my knowledge.

The Chairman. But you did not want him to testify?

Mr. McCabe. No, sir.

The Chairman. Why did you not want him to testify?

Mr. McCabe. Because I did not want him to testify as an officer of the department in opposition to the ruling that had been made by the Secretary and by the three secretaries.

The Chairman. It appeared in the testimony of Dr. Remsen yesterday that the Secretary of Agriculture advised him to give his testimony.

Mr. McCabe. Yes, sir.

The Chairman. At the time that you gave this advice to Dr. Wiley, were you aware of the fact that Dr. Remsen had been requested by the Secretary of Agriculture to give his testimony?

Mr. McCabe. Yes, sir; I was.

[Solicitor McCabe, in advising Dr. Wiley as to whether he could be made to appear before the court at Indianapolis, submitted the following opinion:]

"Under the circumstances, therefore, I have to advise you that it rests in your discretion as to whether or not you will appear and testify in answer to a subpena, since, as stated, failure to do so cannot be regarded as contempt of court, nor be punishable as such. The same is true, of course, of any other employee who may be subpenaed.

Very respectfully,
GEORGE P. MCCABE, *Solicitor.*

[Further questioning brought out the following:]

The Chairman. You stated that you were aware that the Secretary of Agriculture had requested Dr. Remsen to appear?

Mr. McCabe. Yes, sir.

The Chairman. Were you aware at that time that the request for Dr. Remsen to appear had come from Curtice Bros.?

Mr. McCabe. No, sir. I knew it came from their attorneys.

The Chairman. You knew that the request had come from Curtice Bros. to Dr. Remsen?

Mr. McCabe. From Curtice Bros.' and Williams Bros.' attorneys.

The Chairman. And that the Secretary of Agriculture, knowing the fact that Curtice Bros. had requested it, had requested him to give his testimony?

Mr. McCabe. No; I do not think that is a fair statement of it. What I said is this; that I knew the attorneys for Curtice Bros. and Williams Bros. in this proceeding had asked for this testimony.

The Chairman. And the Secretary of Agriculture had requested him to give the testimony.

Mr. McCabe. I knew the Secretary of Agriculture had requested Dr. Remsen to testify.

The Chairman. But you do not know whether the Secretary knew at that time that Curtice Bros. had requested him to give it?

Mr. McCabe. No; I don't know that Curtice Bros. had.

The Chairman. You knew also that the Attorney General had requested Dr. Wiley to give the testimony?

McCabe. The attorney general of the State of Indiana?

The Chairman. Yes.

McCabe. Yes, sir.

DR. BARNARD THROWS LIGHT ON THE PROCEEDINGS

[But by far the most interesting and enlightening testimony in this case was that given by the State Food and Drug Commissioner of Indiana, Dr. Harry E. Barnard, who is also chemist to the Indiana State Board of Health. So clear-cut and illuminating is Dr. Barnard's testimony that we reprint practically all of it, omitting only such parts as are repetitions.]

[*Dr. Barnard's Testimony*]

Mr. Moss: What is your present official position?

Dr. Barnard: Chemist to the State Board of Health of the State of Indiana and state food and drug commissioner.

Mr. Moss: What official positions have you held by appointment in the scientific world?

Dr. Barnard: For several years state chemist of New Hampshire; prior to that time, for a year, I was connected with the Navy Department here in Washington.

Mr. Moss: What were your duties in the Navy Department?

Dr. Barnard: Assistant chemist in the government smokeless-powder factory at Indianhead.

Mr. Moss: Do the statutes of Indiana contain what is generally known as a pure-food law?

Dr. Barnard: They do.

Mr. Moss: State briefly the provisions regulating the use of preservatives in canned food.

Dr. Barnard: Section 2 of provision 7 provides:

> If it [a food] contains any added antiseptic or preservative substances except common table salt, saltpeter, cane sugar, vinegar, spices, or, in smoked food, the natural products of the smoking process, or other harmless preservatives whose use is authorized by the State Board of Health, it shall be deemed adulterated.

Mr. Moss: Do you recall the date when that was placed on the statute book?

Dr. Barnard: March 4, 1907.

Mr. Moss: Has there been, so far as you know, any attempt made in the Indiana Legislature to repeal this pure-food law?

Dr. Barnard: There never has been any attempt made to change it; no.

Mr. Moss: Has this statute been attacked by the press, or has it been approved by the press generally of the state?

Dr. Barnard: The pure-food law and all of its provisions have always been approved by the press of Indiana.

Mr. Moss: How many canning factories are there in the state of Indiana in active operation at the present time?

Dr. Barnard: About 120 canning factories, and in addition I suppose there are about fifty other factories which manufacture food products from raw materials, such as apple butter and products of that kind.

Mr. Moss: Did any of these factories conduct an interstate business?

Dr. Barnard: Nearly all of them do an interstate business.

Mr. Moss: Are any of those large concerns?

Dr. Barnard: Several are among the largest in the country.

* * * * * * *

Mr. Moss: Are goods canned in the State of Indiana conformable to the provisions of the state law as to preservatives permitted to be sold in other states of the Union?

Dr. Barnard: So far as I know, they are.

Mr. Moss: So far as you know, then, goods that pass the law of the State of Indiana as to purity will also pass the laws of any other state in the Union?

Dr. Barnard: So far as I know; yes.

Mr. Moss: What has been the effect of the state law in regard to pure food on the canning industry of the state, so far as stimulating or depressing the growth of that line of business?

Dr. Barnard: I believe the passing of our pure-food law has materially advanced the status of our canneries. They are in a much better position before the country to-day than they ever were before.

Mr. Moss: Is the output of those factories greater now than it was at the time of the passage of this law?

Dr. Barnard: Yes.

Mr. Moss: State the attitude of the packers in Indiana toward the pure-food law.

Dr. Barnard: All the canners of the state are in hearty sympathy with its provisions.

Mr. Moss: Do you state this fact within your own knowledge, having obtained it from conversations with leading packers of the state?

Dr. Barnard: Yes; I know that to be a fact.

Mr. Moss: Has any citizen of the State of Indiana filed suit to have this statute of the state declared invalid?

Dr. Barnard: No.

Mr. Moss: If such suit were to be filed, would the state or federal courts have jurisdiction?

Dr. Barnard: The state courts would have the jurisdiction.

Mr. Moss: As a matter of fact, has any suit been filed in any court to have the provisions of this law declared invalid?

Dr. Barnard: Yes. Such a suit has been filed.

Mr. Moss: By whom was it filed?

Dr. Barnard: Suit was filed on the 19th day of December, 1908, by two companies, the Williams Bros. Co., of Detroit, Mich., and the Curtice Bros. Co., of New York.

Mr. Moss: In what court was this suit filed?

Dr. Barnard: In the Circuit Court of the United States for the State of Indiana.

Mr. Moss: How came the Federal courts to have jurisdiction over a suit affecting a state law?

Dr. Barnard: I think it was because the complainants were foreign corporations.

Mr. Moss: Are either Curtice Bros. or Williams Bros., who appear as complainants in the case, citizens of Indiana?

Dr. Barnard: No; they are not.

Mr. Moss: Does either of the complainants own a canning factory in the State of Indiana?

Dr. Barnard: No; neither owns any.

Mr. Moss: Have you, as state chemist under the operations of our state law, seized goods which have been packed by either one of the complaining firms?

Dr. Barnard: Yes; we have collected a great many samples of goods manufactured by these two firms.

Mr. Moss: How were these goods labeled as to the use of preservatives?

Dr. Barnard: They were always labeled to indicate in certain classes of goods the existence of benzoate of soda to the extent of one-tenth or one-twelfth of 1 per cent.

Mr. Moss: Did you analyze any of these seizures?

Dr. Barnard: Yes; many samples.

Mr. Moss: Upon analysis in the state laboratory what proportion of benzoate of soda was found in those samples?

Dr. Barnard: Various quantities, but in almost every case from two to three times the amount declared on the label.

Mr. Moss: Then, according to your understanding of the regulations promulgated by the three secretaries as to goods which could be sent in interstate commerce, providing they were correctly labeled as to the proportion of benzoate, the goods that you analyzed would have violated those provisions?

Dr. Barnard: I take it they were all illegal.

Mr. Moss: If these firms were to pack their goods, using only such preservatives as are prescribed by our state law, would they have free sale in our state?

Dr. Barnard: Certainly.

. . . .

Mr. Moss: In what form was the suit brought against the state by Curtice Bros. and Williams Bros.?

Dr. Barnard: The plaintiffs came before the judge of the United States court of Indianapolis, asking for an injunction restraining the state food commissioner and the individual members of the State Board of Health from enforcing the pure-food law, and alleging that the pure-food law of the State of Indiana was unconstitutional and void for many reasons.

Mr. Moss: The legal grounds we will place in the record. What I want to develop is that it was for a temporary injunction restraining the state from enforcing the state law.

Dr. Barnard: Yes; that is right.

Mr. Moss: What was the ruling of Judge Anderson on this matter?

Dr. Barnard: He refused to grant the temporary injunction called for.

Mr. Moss: Did he also refuse to dismiss the petition?

Dr. Barnard: He refused to dismiss the petition of the state.

Mr. Moss: What legal procedure followed this ruling?

Dr. Barnard: Later the judge appointed a master in chancery to take testimony as to the facts involved in the petition of the complainants.

Mr. Moss: After this master was appointed did Williams Bros. and Curtice Bros. proceed to take depositions of various witnesses all over the United States?

Dr. Barnard: They did.

. . . .

Mr. Moss: In the taking of those depositions did Curtice Bros. and Williams Bros. take any testimony from any employees in the National Department of Agriculture?

Dr. Barnard: They did; yes, sir.

Mr. Moss: State to the best of your recollection how many employees of the Department of Agriculture gave testimony in this case for the firms of Curtice Bros. and Williams Bros.

Dr. Barnard: With the exception of two or three young men, subjects and clerks, any person who did any work in connection with the benzoate of soda investigation employed by the Department of Agriculture was examined. This included all members of the referee board, chemists, physicians, medical experts, clerks, stenographers, janitors—everyone who had anything to do with the case.

Mr. Moss: About how many in total?

Dr. Barnard: I cannot say exactly, but more than seventy-five.

Mr. Moss: Were Curtice Bros. and Williams Bros. compelled in any instance to apply to a court of justice to secure process to compel these employees, or any one of them, to appear and testify in court?

Dr. Barnard: Not that I know of.

Mr. Moss: Did the State of Indiana secure testimony from any of the employees of the National Department of Agriculture?

Dr. Barnard: Yes.

Mr. Moss: You may state who they were that you desired particularly to testify.

Dr. Barnard: We wished to secure the testimony of Dr. Wiley, chief of the Bureau of Chemistry, and those of his assistants who helped him in his benzoate of soda investigation.

Mr. Moss: Did any of the employees appear voluntarily to give their testimony on the request of the State of Indiana?

Dr. Barnard: No; we found it impossible to get their testimony.

Mr. Moss: Have you any reason to believe that these employees were personally adverse to the giving of such testimony?

Dr. Barnard: No; I think not.

Mr. Moss: Did any of these employees appear finally and testify, or give their depositions?

Dr. Barnard: Yes; after we went to the Supreme Court of the District of Columbia to compel them to testify.

Mr. Moss: When the State of Indiana applied to the courts in the District of Columbia for compulsory process to compel the employees of the Department of Agriculture to appear and testify, did counsel representing the Department of Agriculture appear in opposition?

Dr. Barnard: Yes.

Mr. Moss: In actual test, then, did you find the Department of Agriculture cooperating with the State of Indiana in the enforcement of the pure-food law or operating in opposition to the enforcement of the state laws?

Dr. Barnard: We found the Department of Agriculture opposing the State of Indiana in every move which we made to defend the pure-food law of our state.

Mr. Moss: Now, as to the results of the suit, if the prayer of the Curtice Bros. and Williams Bros. had been granted, what would have been the effect upon the pure-food law of the State of Indiana?

Dr. Barnard: We would have had no pure-food law.

Mr. Moss: It involved the constitutionality, did it?

Dr. Barnard: It did.

Mr. Moss: And its validity?

Dr. Barnard: Yes.

Mr. Moss: And if this suit of theirs had been successful, or if it finally is successful, it will have the effect of striking from the statute books of the State of Indiana our pure-food law, will it?

Dr. Barnard: That is true.

Mr. Higgins: Well, only one section of it, doctor.

Dr. Barnard: No; they allege that the entire law should go out because when the sections to which they object are stricken out the rest of the law would have no force or effect, they claim.

Mr. Higgins: Of course, that is a legal proposition, and, as I understand it, it is still pending in court.

Dr. Barnard: Yes.

. . . .

Mr. Floyd (acting chairman): Are there any other questions by any other members of the committee?

Mr. Moss: I have one or two more questions. Practically the whole case of the plaintiff in so far as the testimony is submitted was made by the United States employees of the Department of Agriculture, was it not?

Dr. Barnard: Very largely so.

Mr. Moss: Now in the whole course of this suit was there any contention on the part of Curtice Bros. or Williams Bros. that food containing benzoate of soda was superior to that which did not contain it?

Dr. Barnard: I think that one witness of the Curtice Bros. Co. made that claim.

Mr. Moss: Their main claim, is, however, that the addition of benzoate of soda is not deleterious.

Dr. Barnard: Yes; that is the contention.

Mr. Higgins: That was the real issue in the case, was it not, doctor?

Dr. Barnard: Not at all.

Mr. Higgins: That is, as to the use of benzoate of soda as a preservative?

Dr. Barnard: It finally developed that that was the reason for the bringing of the case. The real issue in the case was as to whether or not we should continue to enforce the pure food law of the State of Indiana.

Mr. Higgins: But it revolved around the use of benzoate of soda?

Dr. Barnard: Yes.

Mr. Floyd: In other words, the friends of benzoate of soda were willing to destroy the whole law in order to get their product in?

Dr. Barnard: That was it, exactly.

Mr. Moss: The law involved was purely a state law?

Dr. Barnard: Yes.

Mr. Moss: One that was satisfactory to the canning industry of the State of Indiana?

Dr. Barnard: Yes.

Mr. Moss: One under which the canning industry has been growing and developing?

Dr. Barnard: Yes.

Mr. Moss: What is the reputation of the canned goods of Indiana in the markets of the world?

Dr. Barnard: We believe they are superior to all others.

Mr. Higgins: We will concede that they are the best.

Mr. Moss: And this suit to break down this state law was brought by citizens outside the state?

Dr. Barnard: Yes.

Mr. Moss: And having no business investment in the state?

Dr. Barnard: That is correct.

Mr. Moss: And having no material interest in the law except to get the sale of their products, containing benzoate of soda, within the State of Indiana?

Dr. Barnard: That is correct, I think.

[Equally important and interesting was the testimony given by Attorney General Bingham of Indiana. The difficulties he encountered when he attempted to get information and help from the federal government that would aid him in his defense of the pure food law of his state are here plainly described:]

[*Judge Bingham's Testimony*]

Mr. Moss: Please state your full name.

Mr. Bingham: James Bingham.

Mr. Moss: What official position in your state have you held?

Mr. Bingham: Recently, attorney general of Indiana.

Mr. Moss: During what years were you attorney general?

Mr. Bingham: From January 1, 1906, to January 1, 1911.

Mr. Moss: As attorney general of the State of Indiana, you are familiar with the suit brought by Curtice Bros. and Williams Bros. against the State of Indiana in the case involving the pure-food law?

Mr. Bingham: Yes, sir.

Mr. Moss: You will state concisely to the committee just what is involved from a legal standpoint in that suit.

Mr. Bingham: The constitutionality of our pure-food law in Indiana as applied to the use of benzoate of soda as a preservative.

Mr. Moss: Did it involve the interpretation of any federal law?

Mr. Bingham: No.

. . . .

Mr. Moss: What will be the effect on the operation of the pure-food law if the decision of Judge Anderson sustains the prayer of the complainant?

Mr. Bingham: It will practically destroy it.

Mr. Moss: It will practically destroy the law?

Mr. Bingham: Yes, sir.

Mr. Moss: You are of course familiar with the politics of our state. Do you know of any attempt having been made in the Legislature of the State of Indiana to repeal this law since it went upon the statute books?

Mr. Bingham: No. I have never known of any, although I have not been in touch with what has been going on in the committee rooms or anything of that kind, but, on the other hand, I think the policy has been to strengthen the law, not to destroy it.

Mr. Moss: So far as you are acquainted with the press of the state, has it supported or has it been opposed to this law in its present form?

Mr. Bingham: Oh, I think it has always given a cordial support to the law.

Mr. Moss: So far as you are acquainted with the public sentiment of the State of Indiana and the citizenship, is it favorable to or opposed to the pure-food law?

Mr. Bingham: I think it is decidedly favorable.

Mr. Moss: And so far as you have an acquaintance with the canning industries and other industries affected by the operations of the law, what is their attitude toward it in our state?

Mr. Bingham: I understand that it is most favorable and satisfactory. I have, of course, not had personal contact with anybody except a few of them, but I have talked with canners and preservative men, and also the dealers, and they are favorable to the law and exceedingly anxious that the question be decided, so they may know what—

Mr. Moss (interposing): During your term as attorney general, which was four years immediately following the passage of this law, were you called upon to defend any suit brought by any citizen of the State of Indiana to have this law declared invalid?

Mr. Bingham: None whatever.

Mr. Higgins: Your answer is "no"?

Mr. Bingham: None whatever. No suit of that kind.

Mr. Moss: You were called upon, however, to defend a suit brought by citizens without the state, were you not?

Mr. Bingham: Yes, sir.

Mr. Moss: Now, judge, what was the relief which Williams Bros. and Curtice Bros. asked of the federal court?

Mr. Bingham: They sought to have a restraining order issued.

Mr. Moss: Will you state to the committee how it came that the federal court had jurisdiction over this purely state law?

Mr. Bingham: Because it involved a constitutional question—that is, taking property without due process of law, and because of the diverse citizenship of the parties.

Mr. Moss: What answer did Judge Anderson make to this prayer for a temporary restraining order?

Mr. Bingham: He declined to grant the temporary restraining order in most positive terms.

. . . .

Mr. Moss: Will you state again about how much territory you traveled in order to take the various depositions asked for by the plaintiff?

Mr. Bingham: Well, we began taking depositions at Seal Harbor, Me., on Mount Desert Island, and we wound up in San Francisco, Cal.

Mr. Moss: Who paid the expenses of yourself and those who went along in the matter of the taking of these depositions?

Mr. Bingham: The State of Indiana.

Mr. Moss: And it amounted to a considerable amount?

Mr. Bingham: Yes, sir. I don't know exactly how much it did amount to, but I think perhaps the money we spent in going to San Francisco to take Dr. Taylor's deposition may be recovered on proper motion, for the reason that when they took the deposition I was out there and cross-examined him, and they decided after that to bring Dr. Taylor to Indianapolis and not use his deposition taken out West, and I suggested then to the court that at the proper time we would ask to have that cost taxed to the complainants; and I think that should be recovered. Otherwise the money was all paid.

Mr. Moss: Were you aware at that time that the Department of Agriculture was paying the expenses of such members of the referee board and such other employees of the Department of Agriculture as came to Indianapolis and appeared there to testify?

Mr. Bingham: Well, at that time I think none of them had come to Indianapolis. We took depositions first. With perhaps one or two exceptions at least, we took these depositions, especially the far-away depositions, we took those first. I knew from the testimony of the witnesses, the members of the referee board, that they were being paid by the government.

Mr. Higgins: That appears in the testimony, does it not?

Mr. Bingham: It appears in the testimony, and it appears in a private conversation with Dr. Herter, of New York, in talking with him at his cottage at Mount Desert Island, Me. He told me that was true, and my recollection is that he afterwards so testified in the case.

Mr. Moss: When these members of the referee board appeared and gave their testimony, did they qualify as expert chemists or were they testifying in their capacity as members of the referee board?

Mr. Bingham: Oh, they testified as experts and testified as to the results of all their investigations as members of the referee board, and everything else that anybody asked them about.

Mr. Moss: You took quite a number of depositions in favor of the plaintiff in this case—that is, such depositions were taken?

Mr. Bingham: Yes; quite a number.

Mr. Moss: Were any of the depositions taken by Williams Bros. and Curtice Bros. taken from men who were employees of the Department of Agriculture or connected with the Department of Agriculture?

Mr. Bingham: If you say that the members of the referee board and their subjects and helpers, as I call them, were employees, I should say "yes." Now, as to whether or not any of the regular employees of the Department of Agriculture gave depositions, I am not quite sure about that.

Mr. Moss: But these were regular employees?

Mr. Bingham: They testified to having been paid for their services.

Mr. Moss: Within your knowledge, did the Curtice Bros. or Williams Bros. have to appeal to a court of law in order to secure compulsory process in order to have such person appear and testify?

Mr. Bingham: No; they did not have to. I do not know of any, and I am satisfied they did not have to do anything of that kind.

Mr. Moss: Do you know of their making any application for any employee of the Department of Agriculture to testify in behalf of the plaintiffs and that they were refused?

Mr. Bingham: I do not know.

Mr. Moss: You do not know of any such case?

Mr. Bingham: No.

Mr. Moss: On the part of the State of Indiana did you wish to secure the testimony of any employee in the Department of Agriculture?

Mr. Bingham: Yes, sir.

Mr. Moss: Will you state, judge, who it was, if you can recall that, whom you desired to secure the testimony of?

Mr. Bingham: We desired to secure the testimony of Dr. Harvey Wiley, the chief of the Bureau of Chemistry, and of the subjects that constituted the so-called poison squad that served when Dr. Wiley was making his benzoate of soda test, as I should call it, and also the helpers. That would be Dr. Bigelow and his chemist and several other chemists and clerks who helped to make up and tabulate the result of the investigation. I wanted to take all those depositions.

Mr. Moss: To whom did you make your first application for the testimony of those persons whom you wished to give evidence?

Mr. Bingham: Well, I really did not apply to the Agricultural Department first. I may say that I was under the impression that I would have some trouble about having Dr. Wiley come to Indianapolis. I was desirous, if I could, of having Dr. Wiley come in person to Indianapolis and testify before the master. I thought it would be better than to have his deposition. Well, I did apply first to Dr. Wiley. Dr. Wiley said to me that he would prefer that I confer with Secretary Wilson or the Department of Agriculture—I don't know which—with reference to procuring his attendance at Indianapolis, and Dr. Wiley was the first one; and I am not quite sure whether I personally did that or had Mr. Thompson, my assistant, do that. He came down to Washington and had a conference with Dr. Wiley in my absence and at my suggestion—I am not quite clear whether it was myself at first; I think perhaps I wrote Dr. Wiley first; I am not sure about it.

Mr. Moss: Then you did indicate a desire to have Dr. Wiley appear at Indianapolis to testify in the case?

Mr. Bingham: Yes.

Mr. Moss: And coupled with that request was there also a request that the Department of Agriculture should pay his expenses?

Mr. Bingham: Well, I do not think I made any request of that kind. I think I requested the attendance of Dr. Wiley and called attention to the fact that the members of the referee board had testified at the request of the Secretary of Agriculture.

Mr. Moss: What reply did you get from this request for Dr. Wiley's appearance at Indianapolis; was the request granted?

Mr. Bingham: No; the request was not granted.

Mr. Moss: Was it refused?

Mr. Bingham: It was put in this way: That the Agricultural Department had made a report which was contrary to that of Dr. Wiley, and that it might appear that the department would be put in the attitude of not sustaining the referee board or not being in sympathy with its decision—I do not remember the exact language—and suggested that we had better cause process to issue and take his deposition in the regular way.

Mr. Higgins: Do you think that was the suggestion of the Secretary?

Mr. Bingham: It was a letter signed by Secretary Wilson, I remember. That letter, however, was not addressed to me personally. I call attention to that.

. . . .

Mr. Moss: There were some papers, judge, that you desired to secure from the Bureau of Chemistry, were there not?

Mr. Bingham: Yes.

Mr. Moss: Please state whether or not you had any difficulty in securing those papers.

Mr. Bingham: In the matter of securing the papers I called at the department and everybody over there seemed to be kind enough and perfectly willing, providing it was satisfactory to the secretary and Solicitor McCabe, but were under the impression that it was not agreeable to give out the papers, and, as I remember, I prepared a written request as to what I wanted and what I did want was the report of Dr. Wiley on this test—the benzoate of soda test. I explained to those in charge of the department that the referee board's report had already been introduced, a certified copy given by complainants, and that what I wanted was the certified copy of the report by Dr. Wiley, and that I did not want any more than that, that the other was all in and would encumber the record. They took that under advisement, counseled somebody, some attorney was there, and after a considerable time I was given to understand that if the complainants consented that they would furnish the certified copy.

Mr. Moss: That is, if the Curtice Bros. and Williams Bros. were willing——

Mr. Bingham: They did not put it just that way.

Mr. Moss: That, in effect, was the meaning, was it not?

Mr. Bingham: Yes; that was. Then I wrote a rather impudent note—at least I tried to make it impudent; I do not know whether I succeeded or not—to the Agricultural Department, in which I said that the complainants had consented that the department might furnish this information; and then came along a very elaborate report, including—starting in with the beginning of all this benzoate of soda test of Dr. Wiley's, the old order that was to go into effect, and that was reversed, and then the report and the reversal of that order of Dr. Wiley, and then the referee board's report tacked onto it with gold seal and ribbons, and everything necessary to make it appear very formidable. There were about a thousand pages of that report of the referee board, and I objected very seriously to having that forced into the record when I was trying to get only the report of Dr. Wiley, and through the courtesy of counsel——

Mr. Higgins: You mean you objected to the master——

Mr. Bingham: Oh, I called up the department and telephoned to them and told them that what I wanted was a certified copy of this particular report, and they had my written request for it. They knew what I wanted. And then through the courtesy of the counsel for the complainants I finally introduced a copy of Dr. Wiley's report, not certified.

Mr. Moss: I will ask you if the State of Indiana was required to give consent before the report of the Remsen board or any official documents of that kind were introduced?

Mr. Bingham: None whatever.

Mr. Moss: But before you could get this report from the department the complainants had to join you in the request?

Mr. Bingham: Well, they sent over that sort of a statement to me. As I remember, it was on a card or something like that. I am not sure but what that memorandum is among the papers at Indianapolis. I don't remember exactly about it.

Mr. Moss: I will ask you if at any time during the taking of these depositions you received on behalf of the State of Indiana any encouragement or cooperation on behalf of any official of the Department of Agriculture?

Mr. Bingham: Voluntarily, no; but I may say this for Dr. Wiley: When I said to him that I wanted to take his deposition and question him about whether he would testify as an expert or not—I wanted his opinion of the result—he said that he would testify and that he would answer any questions that were put to him; that he would not hesitate to testify to anything that he was able to testify about.

Mr. Moss: He explained to you that he was not in a position to act voluntarily, did he not?

Mr. Bingham: He explained to me with reference to that particular thing that he did not propose to have any padlock put on his mouth. I do not know that I am giving his exact language, but that is practically what he said to me.

Mr. Moss: Now, judge, you did this hard work for the State of Indiana. Was your purpose the excluding of benzoate of soda from being sold in the State of Indiana, or was it to preserve the pure-food law of the State of Indiana?

Mr. Bingham: It was, of course, to preserve the pure-food law of the state.

Mr. Moss: You were making the fight to prevent the pure-food law of the State of Indiana from being stricken from the statute books?

Mr. Bingham: Yes; to keep it from being destroyed on account of its being declared unconstitutional.

Mr. Moss: And in making this fight to save the pure-food law of the State of Indiana did you receive any cordial cooperation on the part of the Department of Agriculture's officials, the heads of it?

Mr. Bingham: I received no cooperation. I have described that.

Mr. Moss: Yes; but I wanted to summarize it. Is there any other statement that you care to make in regard to this matter that you wish to go into the record? I will say to the committee that I did not have time to confer with the judge, and that is the reason I ask him to make any other statement that he wishes to make in order to make the record complete.

Mr. Bingham: Of course I do not know that I am in a position to volunteer anything. I would like to say this: That out in California Dr. Taylor testified fully and I cross-examined him fully, and they reported back that the stenographer had not been able to report the examination correctly; that counsel for complainant had been out there for thirty or sixty days, and much of the work Dr. Taylor testified about was conducted after the attorney got out to California and after the examination out there which they claimed the stenographer did not get an intelligent report of.

Dr. Taylor continued his investigations, and counsel for the complainant continued to remain in California, and when we came to the final hearing before the master at which Dr. Taylor testified in person, he testified to many of the things that he had developed after we had taken his deposition out there and several points which had been raised in my cross-examination when I was out there taking his deposition. Dr. Long, of Chicago, testified, as I remember, that he was not asked by the Secretary of Agriculture to appear and testify, but that he came at the instance of the complainant. I do not remember whether he said he paid his expenses or not. Dr. Remsen and Dr. Herter's depositions were taken at Dr. Herter's cottage at Mount Desert Island, Me.: Dr. Chittenden's deposition was taken at New Haven, and then he came on to Indianapolis afterwards and testified in person.

[Next week additional testimony will be published.]

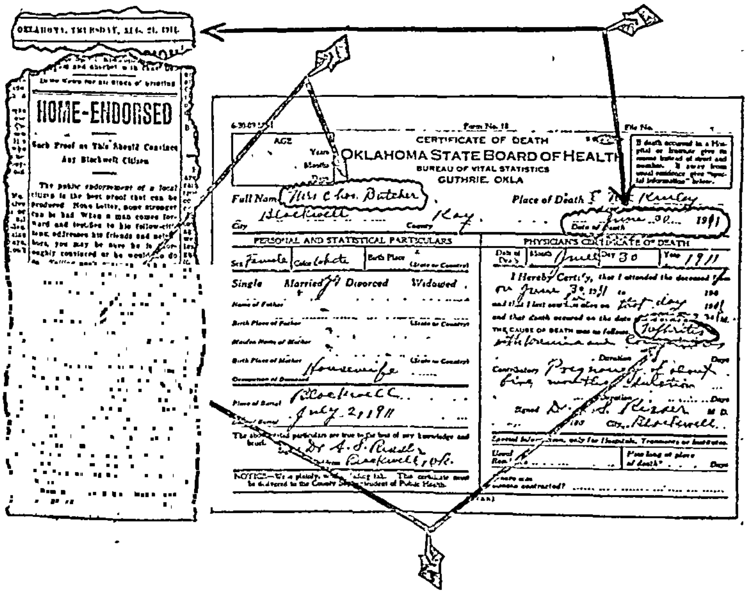
DOAN'S KIDNEY PILLS

A Testimonial that Proved a Boomerang

From a scientific standpoint—which merely means from a standpoint of actual facts—all "patent-medicine" testimonials are valueless. As a business asset of the "patent-medicine" maker, however, they are indispensable. Many nostrum manufacturers attempt to stimulate a local demand for their wares by publishing local testimonials, that is, testimonials from persons in the same locality as that in which the advertisements appear. From an advertising standpoint, there is but one objection to this: the very element that makes a local testimonial of value may, if great care be not taken, prove a boomerang. We present a case of this kind.

The Blackwell (Okla.) *News* for August 24, 1911, contained an advertisement in which a Mrs. Charles Butcher of that city testified to the virtues of Doan's Kidney Pills. As a matter of fact, Mrs. Charles Butcher had been dead nearly two months before the advertisement appeared; and she died of kidney disease!

From the standpoint of the advertiser, this episode merely means poor business management. From the standpoint of the public it means more. Doan's Kidney Pills are a fraud and a dangerous fraud. While they are advertised to "cure all kidney ills" the assertion is a false one. While they are said to be "a simple vegetable remedy," the analysis contradicts this. Here it is:



OKLAHOMA, THURSDAY, AUG. 24, 1911.

HOME-ENDORSED

Such Proof as This Should Convince Any Blackwell Citizen

The public endorsement of a local citizen is the best proof that can be produced. None better, none stronger can be had. When a man comes forward and testifies to his fellow-citizens, addresses his friends and neighbors, you may be sure he is thoroughly convinced or he would not do

CERTIFICATE OF DEATH

OKLAHOMA STATE BOARD OF HEALTH
BUREAU OF VITAL STATISTICS
GUTHRIE, OKLA

Full Name Mrs Chas. Butcher

City Blackwell County Kay

Date of Death June 30 1911

PERSONAL AND STATISTICAL PARTICULARS

Sex Female Color White

Occupation of Deceased Housewife

Place of Burial Blackwell

Date of Burial July 2, 1911

Dr A. S. Risser, Blackwell, Okl.

PHYSICIAN'S CERTIFICATE OF DEATH

Date of Death Month June Day 30 Year 1911

I Hereby Certify, that I attended the deceased

Signed Dr. A. S. Risser M.D.

City Blackwell

Photographic reproduction (greatly reduced) of a Doan's Kidney Pills advertisement that appeared in the Blackwell (Okla.) *News*, August 24, 1911, and a certified copy of the death certificate of Mrs. Charles Butcher, Blackwell, Okla. The advertisement contains a testimonial by Mrs. Charles Butcher, testifying to the value of Doan's Kidney Pills. The death certificate shows that Mrs. Butcher succumbed to kidney disease two months before her testimonial was published.

Oil of juniper	1 drop
Hemlock pitch	10 gr.
Potassium nitrate	5 gr.
Powdered fenugreek	17 gr.
Wheat flour	4 gr.
Corn starch	2 gr

In twenty pills.

Aside from the positive dangers of self-drugging with so-called kidney cures there is an even greater negative danger that people afflicted with kidney disease will neglect proper treatment until they have reached the incurable stage. The viciousness of the "patent medicine" business lies not so much in its assault on the public purse as in its insidious dangers to the public health.

Marriages

LEROY CALKINS PORTER, M.D., Bancroft, Ida., to Miss Maybelle Pearl Houtz of Salt Lake City, Utah, at Houtz Dell, Ida., August 30.

ARTHUR H. MANN, JR., M.D., Baltimore, to Miss Mary E. Elgin of Poolesville, Md., at Baltimore, August 26.

JOSIE HELEN DOBSON, M.D., Washington, D. C., and Dr. Rollin Henry Denniston of Madison, Wis., August 30.

HARRY A. RUTLEDGE, M.D., Baltimore, to Miss Natalie W. Paynter at Alexandria, Va., August 29.

ANDROS GULDE, M.D., Chelsea, Mich., to Miss Eunice N. Jackson of Toronto, Ont., August 10.

EDITH GRACE GRANT, M.D., Greenup, Ill., and Fritz William Graff of Marshall, Tex., August 23.

RALPH C. HAMILL, M.D., Chicago, to Miss Margaret Hunt of Winnetka, Ill., September 2.

LEO STEINER, M.D., to Miss Lilian Lederer, both of Chicago, August 29.

Deaths

George Alexander DeSantos Saxe, M.D., prominent as a genito-urinary surgeon, died at his home in New York City, September 10, from heart disease, aged 35. He was born and received his preliminary education in St. Petersburg, and graduated from the College of Physicians and Surgeons, New York City, in 1898. He was assistant pathologist to Columbus Hospital from 1901 to 1904, and since 1901 has been assistant to the chair of genito-urinary surgery in the New York Post-Graduate Medical School. His society membership includes the American Medical Association; the American Urological Association; the National Association for the Prevention of Tuberculosis; the American Society of Social and Moral Prophylaxis; and the New York Academy of Medicine. Shortly after his graduation he became connected with the *New York Medical Journal,* of which he was assistant editor up to the time of his death. He was also assistant editor of the *American Journal of Urinology* and an editorial writer for several other medical journals, author of a standard work on "Examination of the Urine" and joint editor "Blackboard Headings on Surgery."

William C. Phelps, M.D. University of Buffalo, N. Y., 1866; a member of the American Medical Association; professor of surgical anatomy in his alma mater and familiarly known as "Uncle Billy" for many years to the students of the University of Buffalo; in the early seventies surgeon of the police department; and in 1882 and 1883 health physician of Buffalo; consulting surgeon and president of the staff of the Erie County Hospital and surgeon to the Buffalo General Hospital; at one time surgeon of the Seventy-Fourth Infantry, N. G., N. Y., died at his home in Buffalo August 27, after a long illness following a fracture of the patella, aged 66.

Ernest J. Barnes (license, Ohio, 1896), a practitioner since 1879; a member of, and several times a delegate to, the Ohio State Medical Association; president of the Licking County Medical Society in 1905; formerly surgeon of the Wabash and Columbus, Hocking Valley and Toledo railways; surgeon to the Ohio Electric Railway Company; mayor of Granville, O., and formerly a member of the board of education and a member of the village council of Hebron; died at his home in Granville, August 23, from pernicious anemia, aged 54.

Jesse H. Smith, M.D. Rush Medical College, 1860; for sixteen years a practitioner of Cedar Rapids, Iowa, and since 1869 president of the Farmers' Insurance Company, Cedar Rapids; vice-president of the Cedar Rapids and Iowa City Railway and Light Company; thrice mayor of Cedar Rapids; for four years state senator from Linn County; president of St. Lukes' Hospital since its organization in 1877; died at his home in Cedar Rapids, August 29, aged 74.

George Scott Foster, M.D. University of Vermont, Burlington, 1873; a member of the Vermont State Medical Society; senator from Windham County in 1896; for thirteen years a member of the board of supervisors of the state insane; for fifteen years a member of the local pension examining board and for twelve years superintendent of schools, died at his home in Putney, August 18, from diabetes, aged 63.

Ernest Sargent Pillsbury, M.D. Cooper Medical College, San Francisco, 1897; formerly editor of the *Los Angeles Medical Journal;* secretary of the board of trustees of the College of Physicians and Surgeons, Los Angeles, and secretary of the Los Angeles Academy of Medicine; aged 43; was instantly killed September 3, when his automobile rolled down an embankment near Los Angeles.

T. Artemas Borton, M.D. Starling Medical College, Columbus, O., 1867; a member of the Indiana State Medical Association; a consulting physician to the Orphan's Home of Northern Indiana, Plymouth; for more than fifty years a practitioner of Marshall County; founder of the Plymouth Sanitarium; died at his home in Plymouth, August 25, from senile debility, aged 79.

George B. McGoogan, M.D. Fort Wayne (Ind.) Medical College, 1886; for many years in the government service, first in the weather bureau, later deputy collector of internal revenue and since that time in the diplomatic service; United States consul at Progreso, Mexico; died in a hospital in Mobile, Ala., August 29, from fever, aged 48.

William Blythe Lane, M.D. Bellevue Hospital Medical College, 1864; a member of the Medical Society of the State of New York; acting assistant surgeon United States Army in 1864 and 1865; a director of the Manhattan Life Insurance Company since 1872, and vice-president of the company from 1901 to 1910; died at his home in Brooklyn, August 27, aged 73.

John R. Mauk, M.D. Starling Medical College, Columbus, Ohio, 1869; a member of the Indiana State Medical Association; for twelve years a member of the Wayne County pension board and in 1880 a member of the state legislature; died at his home in Cambridge City, August 29, from carcinoma of the stomach, aged 79.

Henry Arnold, M.D. University of Vermont, Burlington, 1880; a member of the Rhode Island Medical Society; chairman of the executive committee of the Foster Old Home Day, was stricken with cerebral hemorrhage during this celebration, at Foster Center, August 24, and died four hours later, aged 56.

George Faulkner, M.D. Harvard Medical School, 1847; one of the oldest practitioners of Jamaica Plains, Boston; founder of the Faulkner Hospital, Jamaica Plains, which was opened in 1901; a member of the Massachusetts Medical Society; died at his home August 27 from senile debility, aged 92.

Henry Kay Kerr, M.D. Trinity Medical College, Toronto, Ont., 1881; University of Toronto, 1881; a member of the Medical Society of the State of New York; for more than twenty years a practitioner of Hammond; died at his home in Watertown, August 22, from cardiac asthma, aged 54.

John Knox, M.D. Medical College of the State of South Carolina, Charleston, 1878; for many years a practitioner of Mecklenburg County, N. C., and a member of the county medical society; died at his home in Pineville, August 21, from septicemia following a carbuncle of the neck, aged 61.

William H. Scott, M.D. McGill University, Montreal, 1894; a member of the Michigan State Medical Society; for several years a surgeon on transatlantic steamers and thereafter a practitioner of Kalamazoo; died in Borgess Hospital in that city, August 27, from heart disease, aged 41.

Theophilus Steele, M.D. Kentucky School of Medicine, 1865; of New York City; a confederate veteran and lieutenant-colonel on the staff of General Morgan during the Civil War; died at the home of his daughter in Bellmore, Long Island, August 23, aged 77.

Franklin P. Scott, M.D. University of Louisville, Ky., 1871; of Monongahela; for several terms president of the Washington County (Pa.) Medical Society; died in Washington, Pa., August 28, from carcinoma, aged 72.

Cornelius W. De Baun, M.D. Albany (N. Y.) Medical College, 1887; for six terms coroner of Montgomery County, N. Y.; died at his home in Fonda, N. Y., August 18, from cerebral hemorrhage, aged 46.

Guy Clifford Powell, M.D. Louisville (Ky.) Medical College, 1898; of Peoria; a specialist on diseases of the ear; died in Presbyterian Hospital, Chicago, August 25, from rheumatic endocarditis, aged 42.

Fred R. Stoner, M.D. University of Nashville, Tenn., 1896; of Decatur, Ill., died in that city August 18, from the effects of an accidental gunshot wound of the chest, aged 38.

William B. Hooser, M.D. Barnes Medical College, St. Louis, 1902; afterward a clergyman; died at his home in Meriden, Wyo., August 11, from cerebral hemorrhage, aged 35.

William Henry Belknap, M.D. University of Michigan Homeopathic College, Ann Arbor, 1900; College of Physicians and Surgeons, Chicago, 1902; a member of the American Medical Association; died at his home in Greenville, Mich., August 26, from disease of the heart and kidneys, aged 39.

James Douglas Baker, M.D. University of Michigan Homeopathic Medical College, Ann Arbor, 1878; chairman of the executive board of McMinnville, Ore., since 1893; died at his home in that place, Nov. 25, 1910, aged 62.

Charles F. Remme, M.D. Missouri Medical College, St. Louis, 1878; a member of the St. Louis Medical Society; died in his apartments in St. Louis, August 25, from cerebral hemorrhage, aged 62.

Leslie McClain, M.D. Medical College of Ohio, Cincinnati, 1875; a member of the Indiana State Medical Association; died at his home in Terre Haute, August 19, aged 62.

Gaston Gladu, M.D. Tulane University, New Orleans, 1893; of Bremond, Texas; was shot and instantly killed in that place August 19, as a result of a family quarrel.

George W. Dollison (license, Ohio, years of practice, 1896), one of the oldest practitioners of Hocking County, Ohio, died at his home in Logan, August 16, aged 82.

Fred Willard Lester, M.D. Rush Medical College, 1879; for several years a practitioner of David City, Neb., died at his home in Aurora, Ill., August 24, aged 57.

Horace L. Ash, M.D., University of Heidelberg, Germany, 1874; died at the home of his son in Lansing, Mich., January 7, from cerebral hemorrhage, aged 68.

Robert Gordon, M.D. McGill University, Montreal, 1868; for thirty-five years a practitioner of Arlington, Ill., died in Seattle, Wash., August 8, aged 69.

John Kruse, M.D. Berlin, Germany, 1864; for many years a resident of Bozeman, Mont.; died in the Deaconess Hospital in that city, August 18, aged 76.

Warren Wallace Merrill, M.D. Bennett Medical College, Chicago, 1880; died at his home in Rensselaer, Ind., August 29, from acute gastritis, aged 54.

Joseph W. Brinkerhoff, M.D. University of Wooster, Cleveland, Ohio, 1873, of Burbank, Ohio, died in Cleveland, August 16, from heart disease, aged 69.

James M. Bridges, M.D. a member of the Missouri State Medical Association and once its president; died at his home in Joplin, Dec. 31, 1910, aged 74.

William H. Burgesser, M.D. Missouri Medical College, St. Louis, 1876; died at his home in Joplin, Mo., August 23, from cerebral hemorrhage, aged 59.

Anton Posch, M.D. University of Innsbruck, Austria, 1881; died at his home in Round Top, Texas, August 21, from cerebral hemorrhage.

John P. Youmans (license, Ark., years of practice, 1881); a veteran of the Civil War; died at his home in Lewisville, June 8, aged 79.

Joel W. Nixon, M.D. University of Baltimore, Md., 1878; died at his home in St. Louis, August 25, from heart disease, aged 62.

H. Jefferson Foster, M.D. Eclectic Medical Institute, Cincinnati, 1882; died recently at his home in Cucamonga, Cal.

W. E. Jennings (registration, Texas, years of practice, 1907); died at his home in Burnet, August 29, aged 67.

Thomas J. Jones, M.D. Drake University, Des Moines, 1887; died at his home in Des Moines, August 20, aged 57.

Correspondence

Iodin in Sterilization of the Skin

To the Editor:—In view of the fact that in numerous articles which have been recently published on the subject of iodin sterilization of the skin, mention is made of the paper of Grossich, published in the *Zentralblatt für Chirurgie* (October, 1908) [summarized in THE JOURNAL, Dec. 5, 1908, p. 2012], as being the first recorded use of iodin for that purpose, I wish to say that I used iodin for this purpose in 1905 and published a description of my method in THE JOURNAL, "Some of the Uses of Iodin in Surgical Practice," April 14, 1906, p. 1102. My method was described in a paper prepared for the February, 1906, meeting of the Tri-State Society of Virginia and the Carolinas, which was published in *American Medicine*, November, 1906. The method was again described in a paper prepared for the Hot Springs meeting of the Mississippi Valley Medical Association, Nov. 8, 1906, and published in the *Therapeutic Gazette*, May 15, 1907.

JOHN E. CANNADAY, Charleston-Kanawha, W. Va.

Anesthetization of Sleeping Persons

To the Editor:—In THE JOURNAL, July 29, page 428, is a report that chloroform was given to two sleeping children without awakening them. During the winter of 1910 I administered chloroform to a child of about two years of age, while she slept, without her making any show of awakening.

ERWIN C. CARY, M.D., Welcome, Wis.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

CARE OF THE HYPODERMIC NEEDLE

To the Editor:—I use to my entire satisfaction a simple and effective method of caring for the hypodermic outfit as follows: After the needle has been used, it is removed, the barrel is drawn full of 95 per cent. alcohol: the needle is replaced and the alcohol expelled. The plunger is then forced in and out half a dozen times or more and the instrument placed in its case. This procedure is repeated before using. It is a pleasure to find the needle in perfect condition when one wishes to use it. I might add that I have discarded the exasperating wires that are usually found in most hypodermic cases; I depend solely on thorough sterilization with alcohol and find the process satisfactory, saving both time and patience. The outside of the needle and barrel is cleansed with alcohol on absorbent cotton or gauze.

J. C. JENKINS, Lititz, Pa.

ANSWER.—It may be fair to question whether or not our correspondent will secure a clean needle by this method. We understand that this procedure is primarily aimed at perfect cleansing of the needle to avoid rust and clogging. For this purpose pure alcohol is the best, but for sterilization, a partly diluted alcohol may be better. This question was brought up in THE JOURNAL, June 10, 1911, page 1741, and June 24, page 1900. It was stated that full strength alcohol is not as effective a germicide as 70 per cent., and that even 70 per cent. requires ten minutes to kill the staphylococcus. It will be noted that Dr. Jenkins does not specify that he holds the alcohol in the needle for any certain length of time. Is it not better and safer to place the needle in a few tablespoonfuls of water and boil for three minutes to insure absolute asepsis, as well as to secure sterile water?

DIAGNOSIS OF INFLUENZA

To the Editor:—Your editorial on the frequency of mistakes in diagnosis of influenza leads me to ask for the full technic for finding the germ; also such description of the germ as will enable one to identify it when found. Does it have to be grown, or may it be demonstrated in the discharges from the patient? Would it help in its identification if you were to give a photograph of its appearance? Is it necessary before making a diagnosis of influenza to demonstrate the presence of the germ?

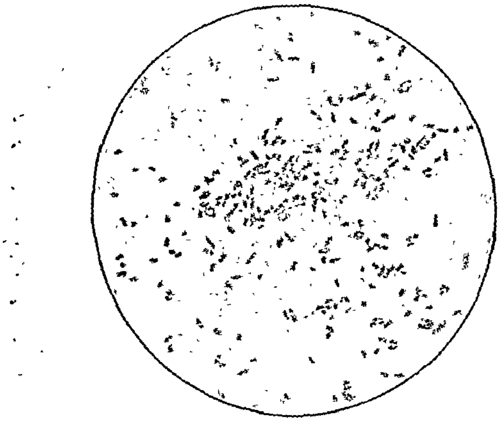
T., Toledo.

ANSWER.—The technic for finding influenza bacilli in various discharges consists in the direct examination of smear preparations and in the cultivation of the organism on suitable culture media. The smear preparations are made by spreading a loopful or a drop of the material to be examined (sputum, pus, cerebrospinal fluid, etc.) on a glass slide or a cover-glass, and allowing it to dry and become fixed in the flame. A very satisfactory and simple stain is fresh dilute carbol-fuchsin made by diluting ordinary carbol-fuchsin (such as is used for staining tubercle bacilli) twenty-five or thirty times with distilled water. This is applied for from two to three minutes, the slide is washed with water, dried and mounted in balsam. When other organisms are present in the material, as is almost always the case with sputum, it is desirable to stain first with Gram's stain and then use dilute carbol-fuchsin as a counter stain. By this method, the Gram-positive organisms such as pneumococci and streptococci are stained dark purple or nearly black and the influenza bacilli, which are Gram-negative, stain light red. The influenza bacillus is very minute, being one of the smallest organisms known. It is about three times as long as it is broad and the ends usually stain deeper than the center. It may be seen inside the polynuclear leukocytes, especially late in the course of the infection. There is no characteristic arrangement of the organisms outside the leukocytes though they are often observed in loose clusters.

The influenza bacillus requires for growth the presence of hemoglobin in the culture medium. A minute quantity is sufficient. As the bacillus usually occurs in sputum, in which practically always other organisms are present, the plate method is used for isolation. In this method, tubes of melted agar, to which a few drops of sterile defibrinated blood have been added, are inoculated with the material, and poured plates are made and incubated. The influenza colonies, should they be present, are visible in twenty-four hours as small, round, non-hemolytic, "dewdrop-like" colonies and are distinctly larger and more numerous around colonies of other organisms such as pneumococci, streptococci, etc. This latter phenomenon, known as symbiosis, is very striking and constant and is characteristic of this organism. The colonies may then be transferred to blood-agar slants and thus pure cultures obtained and further studied.

From the examination of smear preparations alone, one can only be suspicious of the presence of the germ. Cultivation and isolation of the organism should be made for positive identification.

The term "influenza" should be reserved for those conditions caused by infection with the influenza bacillus. There occur not infrequently diseases, especially of the upper respiratory tract, both in sporadic and epidemic forms, which clinically cannot be differentiated from influenza but which are caused by other germs, such as streptococci and pneumococci. For this reason the diagnosis of influenza should not be made without a bacteriologic examination.



The bacillus of influenza

The illustration herewith given is not very satisfactory, as this department is not printed on the calendered paper necessary to bring out the details; for better views the reader is referred to text-books which take up the subject.

The Public Service

Medical Department, U. S. Army

Changes during the week ended Sept. 9, 1911.

Winn, Robert N., major, granted one month and twenty-one days' leave of absence.

Koyle, Fred T., M.R.C., ordered to duty as surgeon of the transport *Kilpatrick*.

Ford, Joseph H., major, ordered to San Antonio, Texas, for duty with the 10th Infantry.

Jones, George B., M.R.C., assigned to duty with the 10th Infantry, San Antonio, Texas.

McAlister, John A., Jr., dental surgeon, reported at Jefferson Barracks, Mo., for duty on examining board.

Ingalls, R. E., dental surgeon, returned to Ft. Douglas, Utah, from detached duty.

Stone, Frank P., dental surgeon, left Presidio of Monterey, Cal., for station at Fort Barrancas, Fla.

Lowe, Thomas S., M.R.C., left Presidio of Monterey, Cal., on three months' leave of absence.

Gunckel, George I., dental surgeon, returned to temporary duty at Fort McPherson, Ga., from leave of absence.

The following changes in the stations of officers of the medical corps and of the medical reserve corps are ordered:

The following named officers will proceed to San Francisco on the transport to sail from Manila, P. I., on or about Jan. 15, 1912, and on arrival report by telegraph to the Adjutant General of the Army for further orders: Major Albert E. Truby, Medical Corps; Capt. Philip W. Huntington, Medical Corps; First Lieut. George H. McLellan, Medical Corps; First Lieut. Arnin Mueller, Medical Corps; First Lieut. Clarence E. Fronk, Medical Corps; First Lieut. Percy G. Drake, Medical Reserve Corps; First Lieut. Ziba L. Henry, Medical Reserve Corps; First Lieut. Herbert L. Freeland, Medical Reserve Corps; First Lieut. Maurice Buchsbaum, Medical Reserve Corps.

The following named officers will proceed to San Francisco on the transport to sail from Manila, P. I., on or about Feb. 15, 1912, and on arrival report by telegraph to the Adjutant General of the Army for further orders: First Lieut. William R. Dear, Medical Corps; First Lieut. Clarence A. Treuholt, Medical Corps; First Lieut. Frederick S. Wright, Medical Corps; First Lieut. Lee R. Dunbar, Medical Corps; First Lieut. Addison D. Davis, Medical Corps; First Lieut. Elsworth Wilson, Medical Reserve Corps; First Lieut. William M. Archer, Jr., Medical Reserve Corps; First Lieut. Henry F. Philips, Medical Reserve Corps; First Lieut. Robert Lemmon, Medical Reserve Corps, First Lieut. Oswald F. Henning, Medical Reserve Corps.

The following named officers will proceed to Manila, P. I., on the transport sailing from San Francisco on or about Jan. 5, 1912, and on arrival will report in person to [illegible] al, Philippines Division, for assignment to [illegible] Freeman, Medical Corps; First Lieut. Thomas [illegible] rps; First Lieut. Edward L. Napier, Medical [illegible] Thomas H. Johnson, Medical Corps; First Lie [illegible] Jr., Medical Corps; First Lieut. William B. Borden, Medical Reserve Corps; First Lieut. Albion McD. Coffey, Medical Reserve Corps; First Lieut. Wilson Murray, Medical Reserve Corps; First Lieut. George R. Clayton, Medical Reserve Corps; First Lieut. Ralph W. Newton, Medical Reserve Corps.

The following named officers will proceed to Manila, P. I., on the transport sailing from San Francisco on or about Feb. 5, 1912, and on arrival will report in person to the commanding general, Philippines Division, for assignment to duty: Captain Frank W. Weed, Medical Corps; First Lieut. Alexander T. Cooper, Medical Corps; First Lieut. Condon C. McCormack, Medical Corps; First Lieut. Madison H. Bowman, Medical Reserve Corps.

McAfee, Larry B., first lieut., is relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., to take effect at such time as will enable him to comply with this order, and will proceed at the proper time to San Francisco, and take the transport to sail from that place on or about Feb. 5, 1912, for Hawaii Territory, and on arrival at Honolulu will report in person to the commanding officer, Fort Shafter, for duty and by letter to the commanding general, Western Division.

The following named officers of the Medical Reserve Corps, recently appointed, are ordered to active duty in the service of the United States, on account of an existing emergency, to take effect Sept. 20, 1911, and will repair to this city at the proper time and report in person on Oct. 2, 1911, to Colonel Louis A. LaGarde, Medical Corps, president of the Army Medical School, to take a course of instruction at that school: First. Lieteunants Leo B. Allen, Morris H. Boerner, William G. Gill, Chester R. Haig, Robert M. Hardaway, Thomas E. Harwood, Jr., Howard L. Hull, George H. Hungerford, Charles P. Kennedy, Harry R. McKellar, Alvin C. Miller, Henry C. Osborn, Omar H. Quade, Charles M. Walson, William F. Wild, Neal N. Wood.

Each of the following named officers of the Medical Reserve Corps is relieved from duty at the station designated after his name, to take effect at such time as will enable him to comply with this order, and repair to this city at the proper time and report in person on Oct. 2, 1911, to Colonel Louis A. LaGarde, Medical Corps, President of the Army Medical School, to take a course of instruction at that school: First Lieutenants Harry H. Blodgett, Fort Riley, Kan.; Thomas W. Burnett, Fort Slocum, N. Y.; Philip B. Connolly, Fort Monroe, Va.; John G. Ingold, Fort Wayne, Mich.; Frederick C. A. Kellam, Jr., Walter Reed General Hospital, District of Columbia; Kermin W. Kinard, Ft. Ethan Allen, Vt.; Douglas W. McEnery, San Antonio, Tex.; Shelley U. Marietta, Ft. Sheridan, Ill.; John W. Meehan, Ft. Howard, Md.; Leopold Mitchell, Washing [illegible] ther R. Poust, Ft. Du Pont, Del.; Guy L. [illegible] s, Me.; William P. J. Ruddy, Ft. Myer, Va. [illegible] Moultrie, S. C.; John W. Sherwood, Ft. Wi [illegible] on, Ft. Adams, R. I.; John H. Trinder, Ft. [illegible] Turnbull, San Antonio, Tex.; Alfred P. Ups [illegible]

[illegible] relieved from duty at Fort Sam Houston [illegible] such time as will enable him to comply with orders to the Philippines Division.

McMurdo, Hew B., M.R.C., recently appointed, is ordered to active duty Sept. 20, 1911, and ordered to Army Medical School, this city, October 9, for course of instruction.

Hess, Louis T., major, granted two months' sick leave of absence.

Hutton, Paul C., major, ordered to proceed to Fort Snelling, Minn., for temporary duty when his services are no longer required at San Antonio, Tex., and then to take station at Fort Howard, Md., as heretofore ordered.

McAfee, Larry B., lieut., relieved from duty at Army General Hospital, Hot Springs, Ark., and ordered to Fort Shafter, H. T., for duty.

Medical Corps, U. S. Navy

Changes during the week ended Sept. 9, 1911.

Ransdell, R. C., P. A. surgeon, detached from the *Baltimore* and ordered to the *Utah*.

Brown, H. L., P. A. surgeon, ordered to the *Baltimore*.

Cecil, A. B., asst.-surg., detached from the naval station, Guantanamo, Cuba, and ordered to the *Marietta*.

Irvine, W. L., asst.-surg., detached from the *Marietta* and ordered to the naval station, Guantanamo, Cuba.

Sanborn, C. F., A. A. surgeon, resignation accepted to take effect from Sept. 5, 1911.

Sutton, D. G., P. A. surgeon, detached from the *Indiana* and ordered to duty at the naval hospital, Annapolis, Md.

Wells, H., medical director, placed on the retired list from Sept 17, 1911.

McDonell, W. N., P. A. surgeon, detached from the *Massachusetts* and ordered to the Kansas.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POSTGRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

[NOTE.—The pamphlets containing the outline of the postgraduate study course for county societies for the coming year are ready for distribution. Secretaries of county societies can secure supplies by writing to the Secretary, Council on Health and Public Instruction, American Medical Association, 535 Dearborn Ave., Chicago.]

First Month—Second Weekly Meeting

CLASSIFICATION OF TUMORS: Work of Hamilton, Ribbert, Borst, Bland-Sutton, Lubarsch. Embryogenetic classification of Adami; Lepidic or "rind" tumors, and hylic or "pulp" tumors. Clinical classification.

FIBROMA: Gross and microscopic appearance, distribution.

LIPOMA: Size, number, distribution, varieties, gross and microscopic appearances.

CHONDROMA: Varieties, distribution, gross and microscopic appearances.

OSTEOMA: Varieties, number, gross and microscopic appearances. Odontomes.

MYOMA: Distribution, mixed tumors, gross and microscopic appearances.

MYXOMA: Gross and microscopic appearances. Secondary changes.

NEUROMA: Pathology, number, distribution.

Ganglionic neuroma. Neurofibromatosis. Molluscum fibrosum.

GLIOMA: Microscopic changes.

REFERENCE BOOKS FOR THE FIRST MONTH

Bland-Sutton: Tumors. Levings: Tumors.
Cathcart: Tumors. Adami: Pathology, vol. i.
Text-Books on Pathology and Surgery.
For a review of the literature on tumors consult the December numbers of *Progressive Medicine*.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

COLORADO: The State Capitol, Denver, October 3. Sec., Dr. David A. Strickler, 612 Empire Building.

GEORGIA: October 10. Sec., Dr. R. E. Hinman, 106½

IDAHO: W , Dr. O. J. Allen, Bellevue.

ILLINOIS: C October 26-28. Sec., Dr. J. A. Egan, Springfield.

IOWA: Capitol Building, Des Moines, September 19-21. Sec., Dr. Guilford H. Sumner.

LOUISIANA: New Orleans, October 19-21. Sec., Dr. A. B. Brown, 108 Baronne Street.

MICHIGAN: Legislative Bldg., Lansing, October 10-12. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

MINNESOTA: State University, Minneapolis, October 3. Sec., Dr. W. S. Fullerton, St. Paul.

MISSOURI: Kansas City, September 25-27. Sec., Dr. Frank B. Hiller, Jefferson City.

MONTANA: The Capitol, Helena, October 3. Sec., Dr. W. C. Riddell.

NEW JERSEY: The State Capitol, Trenton, October 17-18. Sec., Dr. H. G. Norton, 429 E. State Street.

NEW MEXICO: The Capitol, Santa Fe, October 9-10. Sec., Dr. J. A. Massie.

NEW YORK: September 26-29. Mr. Harlan H. Horner, Chief of Examinations Division, Department of Education, Albany.

OKLAHOMA: Muskogee, October 10. Sec., Dr. John W. Duke, Guthrie.

RHODE ISLAND: Room 315 State House, Providence, October 5-6. Sec., Dr. Gardner T. Swarts.

UTAH: Salt Lake City, October 2-3. Sec., Dr. G. F. Harding, 310 Templeton Building.

WYOMING: Riverton, October 9-11. Sec., Dr. A. B. Tonkin.

Alabama July Report

Dr. W. H. Sanders, chairman of the Alabama State Board of Medical Examiners, reports the written examination held at Montgomery, July 11-14, 1911. The number of subjects examined in was 10; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 127, of whom 89 passed and 38 failed, including 1 osteopath. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
University of Alabama, (1910) 75, 75, 75, 76, 79, 79; (1911) 75, 76, 76, 76, 77, 77, 77, 78, 78, 80, 81, 81, 81, 82, 83, 83, 83, 83, 83, 84, 84, 84, 84, 85, 85, 85, 86, 87, 89.4, 90.

Book Notices

AN ATTEMPT TO CORRECT SOME OF THE MISSTATEMENTS MADE BY SIR VICTOR HORSLEY, F.R.S., F.R.C.S., AND MARY D. STURGE, M.D., IN THEIR CRITICISMS OF THE GALTON LABORATORY MEMOIR: A FIRST STUDY OF THE INFLUENCE OF PARENTAL ALCOHOLISM, ETC. By Karl Pearson, F.R.S. Questions of the Day and of the Fray. No. III. Department of Applied Mathematics, University College, London. Paper. Price, 1 shilling net. Pp. 42. London: Dulau & Co., 37 Soho Square, W., 1911.

Last year there appeared, issued from the Eugenics Laboratory, London University, a pamphlet by Professor Karl Pearson, entitled "The Influence of Parental Alcoholism on the Physique and Ability of the Offspring." The conclusion reached and specially emphasized by the author was that there was no such influence. Naturally this would be taken up and made the most of by the advocates of the liquor interests and it excited a rather sharp controversy in the medical journals and in the lay press. The present pamphlet is described as an attempt to reply to certain criticisms in an article in the *British Medical Journal* by Sir Victor Horsley, the well-known British surgeon, and Dr. Mary D. Sturge. Sir Victor Horsley and Dr. Sturge have, according to the showing of this pamphlet, misapprehended some of Professor Pearson's views and statements, as is natural in controversies of this nature. His reply to one or two of their criticisms, however, seems to us not altogether conclusive. At least there is a margin left for doubt as to the value of his methods and their results. His idea in the study was to ascertain whether the alcoholism of the parents had a marked influence on the mentality and physique of the offspring as children, as is stated in the pamphlet. By "offspring" he evidently meant only the children under the age of puberty, but did not specifically state that, probably assuming that it would be readily understood. The charge of Sir Victor Horsley of indefiniteness in the use of the term "offspring" is at least partly justifiable. Professor Pearson's distinction between sober and drinking parents also seems to us an indefinite one. By "sober" he says is not meant totally abstaining. It is applied here to cases in which the use of alcohol "is so moderate, if it exists, that it does not appear to interfere with the health of the individual or the welfare of the home." There are many men who use alcohol to what might properly be called excess and ultimately to their own disaster without showing it in their general appearance or even in the condition of their families. It is the observation of some medical men that their children are liable to suffer in the long run from such parental habits though they may not show it for a long time. Professor Pearson insists on a graded effect of alcohol which we may admit, but there is also a graded idiosyncrasy which is not always directly parallel with its apparent effects. A classification made by officials, or by lay observers generally, on the basis here indicated would not seem to us a very good basis for statistics. In fact one might take cases of parental insanity which, whatever one's theories or heredity may be, is practically hereditary in a very large proportion of cases, and get very similar results to those obtained by Professor Pearson. Comparatively few of the children of insane parents show their heredity before the age of puberty. There is no evidence in the pamphlet before us (we have not seen the original paper) that any attempt was made to estimate stigmata or other mental or physical evidences of degeneracy so far as they could be detected in the immature children of alcoholic parents. Professor Pearson himself admits the possibility of a direct heredity of alcoholism and presumably of other forms of degeneracy in the children of inebriates after the stress of puberty has passed. His line of investigation, it seems to us, was practically defective and the results therefore cannot be considered of great value. He admits a 20 per cent. higher death-rate in the children of alcoholic parents over those of sober parents. But this he accounts for largely by the accidents and unfavorable home environment to which they are subjected by the drinking habits of their parents, which deduction of course may be correct. It is something in the line of Dr. Archdall Reid's contention that alcoholism improves a population by weeding out its degenerates. A large part of the pamphlet is taken up with the discussion of the question of wages as showing that there is no very great difference between the wage-earning capacity of the drinking and the sober workman, but nothing is said about what seems to us one of the most important factors, the equalizing tendency of the trades unions. As to the temper of the attempt to reply to the criticisms, it certainly is open to the charge of being unjudicial, and the reference to authorities is not always happy. We do not know what sort of authority Stöcker is, but his ability to find epilepsy or insanity as an antecedent to nearly all his eighty-nine cases of extreme alcoholism seems a little remarkable. Demme, whom he also quotes, is not a very recent authority and his ideas at the time he wrote in regard to the effects of alcohol on the efficiency of workers as indicated in the quotation given are not in accordance with the best modern medical opinion on the subject. We doubt also whether Crothers, for that is what we take "Chroters" to mean, would entirely agree with Professor Pearson's views.

If the Eugenics Laboratory is to devote its studies to such questions it is to be regretted. Professor Pearson may, as he says, have been entirely without bias at the beginning of his study but that is evidently not his mental attitude at the present time. He is an expert in the handling of statistics, but he does not appear to us always successful in the estimation of the value of the data on which they are based.

Joint Tuberculosis. By Leonard W. Ely, M.D., Consulting Orthopedist to the County Hospital, Denver. Cloth. Price, $2.50 net. Pp. 243, with 72 illustrations. New York: William Wood & Co., 1911.

As the author correctly states in his preface, "The time seemed ripe for a review of more recent knowledge of the subject, inasmuch as the views held were so conflicting that further pathologic study was required." In order to accomplish this, he studied a large number of microscopic specimens from cases, and the results from various modes of treatment. The section on pathology has much to commend it, and is as thorough as one could wish it. His view "that the trend of modern opinion is away from heredity and toward infection from without in cases of tuberculosis" is one generally accepted. The pathologic studies represent much painstaking labor, and are greatly helped by a large number of excellent microphotographs. The only criticism to be offered is that the descriptions of the photographs are often insufficient. Some radiographs are so poorly reproduced that it would have been better to omit them. Especially is this true of Part 1, and, for example, Figure 34.

It is to be greatly regretted that so little reference has been made to the value of the fresh-air treatment and seacoast sojourns.

The second part is devoted to the discussion of tuberculosis of the individual joints. It would have been much more satisfactory to limit the subject of general discussion in Part I, and to elaborate the diagnosis and differential diagnosis of tuberculosis of individual joints, which latter is discussed in a rather incomplete manner.

About forty pages of the book are devoted to histories, which, although they represent much painstaking labor, are of comparatively little value in a book of this kind. The illustrations in general are clear. The volume may be regarded as one of the best in this field of surgery.

Lehrbuch der Augenheilkunde in der Form klinischer Besprechungen. Von Dr. Paul Römer, o.ö. Professor der Augenheilkunde, Direktor der
wald.
Paper. Price, 22 marks. I
erlin:
Urban & Schwarzenberg (N

The student of ophthalmic science cannot complain nowadays of a paucity of either domestic or foreign text-books, compendiums, treatises and monographs on the eye and its diseases. While for Americans practicing in America the products of the domestic pen are far more likely to be of practical value than any foreign manual, however well written, the clearly expressed words of the professor of ophthalmology at Greiswald should not be forgotten when a German authority is to be consulted.

The familiar form which these teachings take—that of talks to a class—are at least pleasant reading and one soon feels that one is under the spell of a competent teacher, investigator and thinker. Römer is probably best known to us as an experimenter and investigator in the realms of applied therapeutics—easily the weakest side of German ophthalmology—and we are not disappointed, especially while reading the chapters on treatment, to find that Römer deals more extensively and intelligently with most eye diseases (as we see them) than does the average compiler or writer of German text-books. The various diseases of the eyelids, conjunctiva and cornea are considered at as great length as the limitations of a schoolbook permit, while the bacteriology of the eye has received even more attention than is commonly given to it in works of this sort. Quite naturally, the treatment of trachoma is completely considered by a man who was probably the first to show us how jequirity could be effectively and safely administered in this serious and intractable disease.

For some occult reason the methods employed in teaching refraction to students, both undergraduate and postgraduate, in German universities are such as cannot be regarded as adequate for American physicians; even our clinic patients demand and usually receive more careful attention to their refractive errors and muscular anomalies than is expended on the corresponding class in Germany. This defect, as we regard it, is reflected in most German treatises, which would, indeed, be false guides for American practice. Römer's lectures form no exception to the rule, the subject of "glass-fitting" being dismissed in the usual light and airy fashion through the reading of a few pages of print.

On the other hand, we are well pleased with the manner in which the neurology of the ocular apparatus is taught and by the discussion of migratory ophthalmia. These and many other subjects are fully and intelligently dwelt on.

The illustrations, colored as well as black and white, are not up to the average; most of the former are useless and many of the latter inadequate to furnish any practical idea to the reader. Some errors in proof-reading are noticed; for instance, Landolt and Weeks are transformed into "Landoll" and "Week."

Die Massenverhältnisse des Herzens unter pathologischen
ntomische Untersuchungen. Von Sofus
43, with illustrations. Christiania:
Jacob Dybwad, 1911.

Numerous studies have been made of the size of the heart under normal and pathologic conditions. The difficulties in the way of obtaining accurate results are great, and many of the methods are faulty. Failure to take into consideration the amount of surrounding fat, or the stumps of large vessels may be cited as instances of these inaccurate methods. Widerøe has tried to overcome the objections to these various methods and by following out his own, which is modeled on that of W. Mueller, he has reached results that he regards as fairly trustworthy. His tables show a careful study of the age of the patient, the height, weight, chest measure; with details as to the heart, such as weight as a whole, weight and measurements of the various parts such as ventricles, auricles, septum ventriculorum, etc. The diseases with which the patients were affected are known and there is a consideration of the size in relation to the pathologic conditions. The monograph is a real contribution to our knowledge of this subject and should be consulted by one interested in this topic. There is a good bibliographic index, with numerous references to the literature scattered throughout the text.

The Healthful Art of Dancing. By Luther H. Gulick, M.D., Author of "The Efficient Life," etc. Cloth. Price, $1.40 net. Pp. 273, with illustrations. New York: Doubleday, Page & Co., 1910.

Dancing is such a popular recreation that there seems little need for a book advocating it, unless it be a plea for its rational use. This is what Dr. Gulick has made. He explains the inborn appreciation of rhythm, and his contribution ought to help to remove some of the evils which have been grafted on to this form of recreation. The folk dances which mean so much in European life and which are being revived throughout the United States with wholesome effect are explained and portrayed, adding greatly to the interest of the book.

Handbook of the Trees of the Northern States and Canada East of the Rocky Mountains. By Romeyn B. Hough, B.A., Author of "American Woods." Cloth. Price, $6. Pp. 470, with illustrations. Lowville, N. Y.: R. B. Hough, 1907.

This book will be of value to those who wish to identify the trees of this country, and all lovers of Nature will appreciate it. For each tree there is a full-page picture of the leaves, with either the flower or the fruit, or both, while the opposite page, which contains a general description of the tree, shows also the trunk, a cross-section of the wood and distribution of the species, indicated on a map of the United States. The pictures are excellent and give evidence of much painstaking work in their preparation. The preface gives a glimpse into this labor of the author when he speaks of the difficulty he had some years in finding the flowers of certain trees; it seemed that there were no blossoms that year and the author traveled far in his search. The book also contains a synopsis of the families and genera represented, with analytical keys to enable one to find the species. A glossary and a good index add to the value of the book.

Kurzgefasste chirurgische Operationslehre (Operationskurs). Für Studierende und Aertze. Von. Ad. Oberst, Assistent an der Chirurg. Klinik und Privatdozent für Chirurgie an der Universität Freiburg i. Br. Paper. Price, 7 marks. Pp. 198, with 232 illustrations. Berlin: S. Karger, 1911.

The only criticism which can be made on this, one of the newer German books on operative surgery, is that the subject has grown to be too large to be covered in as few pages as is attempted in this work. In its favor, however, are its illustrations, especially those which are intended to help elucidate the little details of technic, which are not ordinarily shown, are very clear and well reproduced. Throughout the book only the essentials of each operation are given. An excellent description of the osteoplastic method of amputation, according to Bier, is one rarely seen in the newer books on this subject. It can be recommended as a book for beginners.

Tuberculosis as a Disease of the Masses and How to Combat It. Seventh American Edition. Prize Essay by S. Adolphus Knopf, M.D., New York, Professor of Phthisio-Therapy at the New York Post-Graduate Medical School and Hospital. (International Prize Awarded by Committee of the International Congress to Combat Tuberculosis as a Disease of the Masses, at Berlin, July 31, 1900.) Paper. Price, 25 cents. Clóth. Price, 50 cents. Pp. 122, with 64 illustrations. New York: The Survey, 105 E. Twenty-Second Street (1911).

The new edition of this essay is considerably enlarged and improved, and will doubtless prove as useful in the future as the other editions have in the past. The changes are chiefly in the application of the outdoor methods to sleeping facilities and the expansion of the outdoor school. A new chapter on school hygiene is introduced.

Alcoholic Fermentation. By Arthur Harden, Ph.D., D.Sc., F.R.A., Head of the Biochemical Department, Lister Institute, Chelsea. Cloth. Price, $1.25 net. Pp. 128, with illustrations. New York: Longmans, Green & Co., 1911.

This is another one of the valuable monographs on biochemistry written by specialists in their respective lines and edited by R. H. Aders Plimmer and F. G. Hopkins. It gives one extreme pleasure to find this subject of such general interest and extreme importance covered in so concise and yet in so comprehensive a way. The work is made especially valuable in that it gives a very good bibliography, and in that it is a very complete review of the exhaustive work of Harden and Young on alcoholic fermentation.

Yellow Fever and Its Prevention. A Manual for Medical Students and Practitioners. By Sir Rubert W. Boyce, M.B., F.R.S., Holt Professor of Pathology, University of Liverpool. Cloth. Price, $3.50 net. Pp. 380, with 61 illustrations. New York: E. P. Dutton & Co., 1911.

This is a thorough work by an author who has had a wide experience in connection with the epidemics of yellow fever in the West Indies, in New Orleans and on the west coast of Africa. The history of the disease in these various regions is first considered, then follows a treatise on the symptomatology, diagnosis, pathology and prophylaxis of the disease. The book is well illustrated and will be welcome to sanitarians, especially those who are interested in tropical medicine.

Medicolegal

Revocation of License for Fraudulent Advertising as Unprofessional Conduct—Construction and Validity of Statute

(Aiton vs. Board of Medical Examiners of Arizona, 114 Pac. R. 962.)

The Supreme Court of Arizona affirms a judgment of the District Court sustaining a demurrer to a petition for a writ of certiorari to review the proceedings of the board which resulted in the license of the petitioner to practice medicine in that territory being revoked [i. e., the license remains revoked]. The revocation was after due notice and a hearing, based on an affidavit filed with the board, charging the petitioner with having been guilty, since the license was issued to him, of unprofessional conduct rendering him unfit to practice medicine in the territory, in that he wilfully and knowingly published in a newspaper an advertisement of remarkable cures claimed to have been accomplished by means of certain mineral waters and preparations used and controlled by him, and claiming that such waters and preparations would cure incipient tuberculosis, systemic catarrh, catarrh of the head, Bright's disease, diabetes, rheumatism and numerous other diseases. The advertisement was set forth in full in the affidavit, and it was charged that the publication was made for the purpose of soliciting and procuring wrongfully and fraudulently patients to submit themselves to medical treatment by him; that certain of the statements contained in the advertisement were false, and were known to the petitioner to be false when he made them, and were published with the intent to deceive the public and to impose on the credulous and ignorant.

The question presented by this appeal was the validity of the provision in the statute that: "Upon proper proof to the Board of Medical Examiners of Arizona that the holder of any license issued under the provisions of this act has been guilty, since the issuance thereof, of any grossly immoral or unprofessional conduct rendering him or her unfit to practice medicine in this territory, or has been convicted of any felony, said board shall, after due notice to such holder and full opportunity to him or her to defend against or refute such charges, revoke and cancel such license. . . ." It was contended that the statute, since it does not declare what shall be considered unprofessional conduct, is void for uncertainty. It was argued that "the term 'unprofessional conduct' is so vague and indefinite that no one can be certain just what it embraces. It might be declared to include a breach of professional ethics, irrespective of any moral turpitude, and might be declared to include acts of so trivial a nature and of so little importance as to wholly preclude any of the elements of a crime."

The petitioner attempted to distinguish certain cases which hold valid statutes conferring on boards power to revoke the licenses of those found guilty of immoral conduct from this on the ground that the term "immoral conduct," while in a measure indefinite, "contains an element of moral turpitude or disregard of the settled ideas or principles of morality, and are very easily recognized, by reason of their being a breach of what we all know to constitute moral conduct," but that "unprofessional conduct does not consist simply of breaches of moral conduct, does not necessarily include moral turpitude, and might consist of anything temporarily frowned on by any board of physicians temporarily in power." His position finds support in decisions by the Supreme Courts of Kentucky and California and the Court of Appeals of the District of Columbia.

But this court cannot agree that the meaning to be given the term "unprofessional conduct," as used in this statute, is that suggested. It thinks it should be held to mean that which is by general opinion considered to be grossly unprofessional because immoral or dishonorable. This court cannot perceive that the petitioner's interpretation is tenable or could have been contemplated by the legislature when the language employed and the purpose of the legislation is considered. "Grossly immoral and unprofessional conduct" excludes the idea that a license may be revoked for trivial reasons or for a violation of what might be regarded as mere professional ethics.

Giving the words the construction this court does, the question of the validity of the statute is foreclosed by the decision of the Supreme Court of the United States. In Meffert vs. State Board of Medical Registration & Examination et al., 66 Kan. 710, the action of a board in revoking a license of a physician was upheld under a statute giving it the power to revoke the license of one guilty of gross immorality. On an appeal to the Supreme Court of the United States, the judgment was affirmed without discussion. Meffert vs. Packer, 195 U. S. 625. In that case the statute does not define what shall be considered gross immorality. Its ascertainment if left to the common judgment as to what is grossly immoral, as the Arizona statute leaves grossly unprofessional conduct to be ascertained. See, also, State vs. Board, 34 Minn. 391.

It is too well settled to admit of discussion that the state, in its exercise of the police power, may prescribe the qualifications of those who are permitted to practice medicine, and may commit to a board created by it the authority to ascertain whether an applicant for permission to practice possesses the requisite qualifications, and also the power, after notice and opportunity to be heard, to revoke the license of any who become disqualified either morally or intellectually.

Communications to Physicians Sent to Make Reports Not Privileged

(Chicago, Indianapolis & Louisville Railway Co. vs. Gorman (Ind. App.), 94 N. E. R. 730.)

The Appellate Court of Indiana, Division No. 2, holds that in an action against a railway company for personal injuries communications made to a physician or surgeon who was sent merely to make an examination and report on it are not privileged. The court says that the evidence disclosed that the witness was a surgeon of the railway company at the time of the injury; that he told the injured man (plaintiff) that he was requested by the station agent to visit him, and make an examination so that he could make the ordinary report as surgeons are required to make to the company in cases of that kind; that he was there for the purpose of making an examination as the physician of the railway company to make his report to the railway company, and that he did make an examination as such physician of the said company, but that he did not prescribe for the plaintiff, and had nothing to do with the case as to treatment. In other words, it was evident that his visit was purely on a business matter, and not in a professional capacity, and that the plaintiff so understood the purpose of his call. Under such circumstances there were no privileges protecting a statement made to him by the plaintiff, such as that he heard the train coming, but thought he had time to get over.

Parents Not Liable for Med[illegible] Rendered to Emancipat[illegible]dren

(Brosius vs Barker [illegible] (Mo. App.), 136 S. W. R. 18.)

The Springfield (M[illegible]is.) Court of Appeals affirms a judgment for the defendan[illegible] in this suit of a physician to recover from a father fo[illegible] for medical services rendered to his son, about 20 years [illegible] of age, in a distant state. The son had left his father's [illegible]ome in Missouri and gone to Oregon, where he was taken sick with typhoid fever, and, because he claimed to be without money, the plaintiff, a physician, sent him to a hospital and assumed the charges due the institution for the care of the patient. The father, in answer to a letter notifying him that his boy was there sick, wrote to the superintendent of the hospital, saying, "I have a dear boy in your institution sick with fever. I have sent him some money and will send more soon. You will give him all the attention you can and greatly oblige a father so far away, and kindly let me know from time to time how he is getting along."

The father's defense to the plaintiff's suit for his own services and the balance of account due the hospital, which had been assigned to him, was that he had previously emancipated his son and was not liable for his care. The court thinks that [illegible] evidence was sufficient to require a submission to the jury [illegible]he defense of emancipation, and holds that, as they found [illegible]he father thereon, the further question of whether the [illegible] should pay the plaintiff for the services he and those associated with him rendered in caring for his son while he was sick and perhaps would have perished had such services not been rendered, must be left to the interior forum, as the tribunal of conscience has well been called.

The plaintiff, the court says, knew at the time the defendant's son applied to him for assistance that the boy was not living with his father. He was informed that the father lived in Missouri and therefore it seems to the court that the arrangement between the father and son under which the boy had left home was a matter that the plaintiff should have inquired into before rendering the services to the boy on the credit of the father. He must have known that sometimes children who have good homes and are supplied with all the necessaries and the luxuries of life become dissatisfied, and without any reason or excuse leave home, and that under such circumstances it would be unjust to hold the parent liable on any contracts made by the minor. It was not necessary that the plaintiff should have had actual knowledge that an arrangement existed between the father and son under which the father was released from liability.

Nor does the court consider that the defendant was rendered liable by his letter, as there was nothing in the letter agreeing to pay for the services rendered, and when it was written a contract existed between the plaintiff and the son relating to the services sued for in this case, and there was no evidence that the letter in any wise changed the relation of the parties or the terms of the contract under which the boy was then being treated, or that any additional attention was given the boy on account thereof. On the contrary, the statement is found to the effect that some money had been sent to the boy and more would be forwarded. If the father intended to legally bind himself for the payment of the plaintiff's bill, he did not so state.

Admissible Evidence of Illegally Prescribing Cocain

(Stanley vs. State (Ga.), 70 S. E. R. 894.)

The Court of Appeals of Georgia affirms a judgment convicting the appellant Stanley of illegally prescribing cocain. The court says that the act on which the indictment was framed makes it a penal offense for any practitioner of medicine to furnish to or prescribe for the use of any habitual user of the same any of the narcotic drugs therein mentioned, unless the person for whom the drug is furnished or prescribed is under his professional care and such drug is deemed necessary for his proper treatment. In other words, the statute makes the controlling question one of good faith on the part of the practitioner of medicine in furnishing or prescribing the drug; the issue being whether he does so in good faith to a patient, or whether the prescription is made for the purpose of evading the provisions of the act. The accused in this case contended in his defense that the habitual user of the narcotic drug in question was a patient of his and under his treatment, and that he prescribed cocain for her because he deemed it necessary for her proper treatment. The state contended that the act was not in good faith, but was done for the purpose of evading the provisions of the statute. Any testimony that would tend to illustrate this issue would be admissible in evidence, and testimony that the accused made other prescriptions of a similar character, for many different persons, was admissible in evidence for the purpose of establishing the criminal intent.

Admissibility in Evidence of Record Cards

(Douler vs. Prudential Insurance Co. (N. Y.), 128 N. Y. S. 396.)

The Second Appellate Division of the Supreme Court of New York says that this was an action on an insurance policy on the life of one Margaret Douler, who died of pulmonary tuberculosis in December, 1909. The application for the policy was made July 22, 1909, and the company undertook to prove that at that time, and for a considerable period before, the insured was suffering from pulmonary tuberculosis and knew it. In the attempt to prove that defense, the company called as a witness a physician who was in 1908 in attendance at a public dispensary, in which capacity he had made certain entries on a record card, which contained answers to questions put by him to a woman patient who had given the name of Margaret Douler. He had made certain entries on the card when the patient called at the clinic at various times in October, 1908, and he swore that these entries were true when made, although he no longer had any personal recollection of the matters so entered. The company offered the card in evidence, but the evidence was rejected on the ground that there was not sufficient proof of identity between the insured and the patient, and on the further ground that the record card was not competent evidence, even if identity be assumed. A similar question arose as to the introduction of another record card, kept by a witness who was a nurse in the employment of the board of health, relating to the case of a patient known as "Margaret Douler." That card was likewise excluded when offered in evidence. The court holds that the rejection of these cards was reversible error. As to the identity of the patient at the clinic with the person insured in the policy, similarity of name made a *prima facie* case of identity, according to long-established rules of law. And while these record cards were not competent evidence of their contents simply as records, yet where it was shown that the entries thereon were made by the witness at the time of the happenings described as taking place in his presence, and were honestly made by him, such entries might be admissible where the witness had ceased to have any personal recollection of the facts in question. There was also other testimony offered and received to show that the insured had pulmonary tuberculosis for some time prior to the application for the policy, and the exclusion of the record cards deprived that evidence of some corroboration, and was therefore not harmless.

Validity of Act Making Unlawful Possession of Opium, Etc.

(*Ex Parte Yun Quong (Cal.), 114 Pac. R. 835.*)

The Supreme Court of California in this case holds constitutional the statute of that state which makes it unlawful for any person to have in his possession any cocain, opium, morphin, etc.; or any preparation thereof containing more than 2 grains to the fluid ounce, except on the written order or prescription of a physician, dentist or veterinary surgeon licensed to practice in the state, or unless such possession is that of a jobber, wholesaler, manufacturer to pharmacies, retail pharmacy, physician, dentist or surgeon licensed to practice in the state.

Yun Quong had been arrested for having in his possession a certain preparation of opium prohibited by the act, and attacked the validity of the law, insisting that opium is property and that the act making the mere possession of it a crime is an infringement on the rights of liberty and property. But the court declares that if the belief that the use of opium, once begun, almost inevitably leads to excess may be entertained by reasonable men—and the court does not doubt it may—such belief affords a sufficient justification for applying to opium restrictions which might be unduly burdensome in the case of other substances, as, for example, intoxicating liquors, the use of which may fairly be regarded as less dangerous to the users or to the public. Assuming, as the court must, that the legislature acted on some such view, the restrictions on the right to possess the drugs named in the act cannot be said to be clearly unreasonable or unnecessary for the protection of the public from the evils against which the legislation in question is aimed.

Provision for Physician on Jury in Lunacy Inquests not Unconstitutional

(*State vs. Linderholm (Kan.), 114 Pac. R. 857.*)

The Supreme Court of Kansas holds that the statute of that state providing for a jury, in lunacy inquests, of four persons, one of whom must be a physician, does not violate the right to a jury trial which is guaranteed by the Constitution. The court says that although the hearing of a case of this kind is ordinarily designated as a "trial," it is not so in the sense of the Constitution. The proceeding is merely an inquest, conducted primarily for the benefit of the person whose mental state is in question, and it bears no resemblance to an action, either civil or criminal.

7 Eclampsia. M. Dillon, Fairfield, Mo.
8 Thyroid and Parathyroid Glands. C. Geiger, St. Joseph, Mo.

2. **Abdominal Pain.**—The conclusions deduced by Funkhouser from the study of abdominal pain are: To bear in mind that pain in itself does not tell the whole story, but merely puts the physician and patient on their guard. That there is grave danger following the administration of narcotics which have a great tendency to mask the true condition. That pain is not infallible as to the site of disease. That the initial pain is, in many cases more important than the subsequent diffuse pain that follows. That it is the duty of the physician to educate his clientele relative to abdominal pain, especially should it be the province of that type of medical man, the family physician, who is rapidly disappearing, *triste dictu*, to inform the laity of the significance and the danger of the neglect of abdominal pain.

3. **Death of Fetus in Utero.**—For the determination of fetal death there are, Tilles says, the signs first noticed by the mother, then those observed by the obstetrician both as concerns the mother and the state of the fetus. Observations and sensations on the part of the mother are an absence of fetal movements, heaviness and coldness in the lower abdomen, the feeling of a foreign body in the abdominal cavity, which changes positions with the maternal movements; also a general feeling of coldness or real chills may occur, the breasts are noticed to become smaller, the gradual abdominal enlargement ceases to be noted and becomes stationary or sinks, due to lack of tonicity of the uterus and lacking the resistance of the fetal parts; there is a vague feeling of malaise and languidness characterized by loss of appetite, feeling of lumbago or fatigue, with possibly, in women of delicate nature, a slight evening elevation of temperature. On the part of the obstetrician is noted the absence of fetal heart sounds established after repeated trials, an unusual flabbiness of the uterus instead of the normal resiliency and compressibility, absence of uterine contractions, a possible discharge of meconium, fetid discharges, or flatus from the uterus. Vaginal examination reveals little, as after maceration has occurred the small parts are difficult to feel. The uterus may be hard to differentiate from an abdominal cystic tumor. Knapp claims to have found acetone in the urine, but it has not been confirmed by later experiments. When the cervix admits a finger the relaxed and overlapping condition of the fetal skull bones may be palpated. The effect on the mother is practically *nil* with the exception of the few clinical symptoms mentioned above, unless the fetus undergoes putrefaction with absorption of small parts, the bones then by ulcerative processes attempting to be discharged through the bladder, vagina or rectum, or externally through the abdominal wall.

4. **Eclampsia.**—The treatment employed by Mosher looks to early evacuation of the uterus, as the ovum or fetus is the source of the toxins and statistics show lower mortality after labor. He says that preliminary to delivery, it is best to avoid the use of chloroform during the convulsions; puncture should be made of the membranes to hasten spontaneous dilation and also to lower blood-pressure. Inject veratrum, 15 to 20 drops of the fluid extract, hypodermically and give an enema of warm milk with 40 to 60 grains of chloral. On the base of the tongue place two drops of croton oil. Better,

if it can be done, wash out the stomach and inject through the tube 2 ounces of castor oil with 2 drops of croton oil. Sweating should be induced by hot packs or sweat cabinet for thirty minutes, using ice to the head while heat is applied to the body. A pint of normal salt solution should be injected subcutaneously, or several quarts may, in the emergency, be thrown into the bowel. This sweat and salt injection is to be alternated every hour, provided there is an equillibrium kept between solution injected and sweating. Nitroglycerin if convulsions recur. If patient can swallow she should be given concentrated salts, a dessertspoonful dose every fifteen minutes until catharsis follows. Cups, venesection or leeches may be used if congestion of chest, cyanosed face or sterterous breathing occurs. If medical means fail, manual dilation by Harris' method, followed by forceps or version, are to be considered in each individual case.

17 Electrotherapeutics. F. E. Clark, Logan, Utah.

15. **Gastrectasia.**—The most satisfactory treatment of gastrectasia in Miller's opinion is massage. He has used machine massage for nearly six years. It has proven efficient in more than forty cases. Miller has not had a complete failure, and in two cases only was the result but partial. Both the partial cures were tuberculosis patients. Few cases need more than a three-month period to be cured, and so far as Miller has been able to follow his cases the results are permanent. One patient was treated five months before all subjective symptoms disappeared. Miller had occasion to examine the patient a few weeks ago and found him remaining well. Twenty months have passed since his treatment. When treatment began, the lower curvature was almost two finger-widths below the navel, when discharged, the curvature was three finger-widths above. The course given consists of daily treatments of five to seven minutes each for the first month, three treatments a week for the second month, and one or two treatments per week for the remaining four weeks. Miller requires all patients to remain the ninety days under treatment, and few less responsive cases a longer time. A rigid dietary is carried out and is regarded a part of the treatment. When the stomach is ptosed, the vibratory treatment will not restore it, though in some cases decided improvement has been noted. The displaced stomach must be otherwise cared for. Miller uses either the Spivak bandage or the moleskin adhesive apron belt.

27 and 32. Abstracted in The Journal, May 20, 1911, pp. 1505 and 1506.

29. **Paralysis of Upper Extremity.**—Jacobson illustrates some usual and unusual conditions encountered by presenting the histories of a few cases. I. Fracture of humerus with angulation; nerve not apparently damaged, but adherent to callus for distance of 2 inches; separation of nerve; prompt and complete recovery from paralysis. II. Lacerated wound implicating the musculo-spiral nerve associated with scalp wound and injuries to the shoulder-joint. III. Fracture of the neck of the scapula; displacement of the head of the bone; pressure on and adhesions to the brachial plexus of nerves; compete paralysis of sensation and motion; operation; immediate improvement. IV. Complete division of the fifth cervical nerve; its secondary suture; slow restoration of motion and sensation.

Jacobson contends that when a nerve has been simply stretched over or caught between fragments of bone or entangled in a callus or bound down by adhesions and when no visible damage to the nerve substance has occurred the return of functional activity is prompt and satisfactory without the energetic and long-continued use of such therapeutic measures as electricity, massage, hydrotherapy or the like. But when a nerve has been evidently damaged and most certainly when it has been completely severed the after-treatment is quite as important to the restoration of its functions as is the surgical operation which seeks to remedy the local damage done. It must also be thoroughly understood that whether primary or secondary suture has been undertaken the long-continued application of these measures will be found necessary. Many months may elapse without apparent improvement. The treatment must not be abandoned. The end-result will well reward the effort. Secondary suture has been performed as late as nine, eleven and fourteen years after the receipt of the injury and marked benefit has attended the surgical treatment.

36. **Heroin Habituation.**—The authors believe that the prevalence of the habit is steadily growing, especially since there is now a greater difficulty in obtaining, without prescription, preparations containing the more active opium compounds. From the statements of their two patients there is a certain sense of stimulation and well being induced by heroin which surpasses in its delight that experienced from morphin and they assert that the habit is quite common among their associates. Apparently, judging from these two instances only, the immediate habit is broken with much less suffering and greater ease than morphinism or cocainism and the pathologic and physiologic effects are much less serious than in the more frequent habits.

40, 41 and 42. Abstracted in The Journal, Nov. 5, 1910, p. 1672.

43. **Carcinoma of Uterus.**—Montgomery emphasizes that cancer is an insidious disease, the advent of which is not discovered sufficiently early by the symptoms which are usually considered as indicating it, and that the practitioner should be on the alert for signs which will denote its appearance much earlier than those on which the profession is accustomed to depend.

45. **Physician and Public Health.**—The physician in his professional life is frequently called on to render services without full and sometimes without any compensation. Anders says he should give his best under all circumstances, for by so doing he is constantly growing in power, capacity and efficiency. Such a one, in comparison with a selfish spirit, will also in the end attract larger compensation. It has been wisely said that the man who refuses to do more than he is paid for soon becomes as small as his earning capacity. On the other hand, he who earns more than his compensation thereby makes himself greater than his salary. By rendering much service to both patients and the public, physicians in turn receive much.

46. **Medical Profession To-Day and Business End of It.**—The profession as a whole does not, in Nutt's opinion, wield the influence it should in a community, for the betterment of humanity and the eradication of superstition and quackery. If all the licensed medical men were united in one body, like other organizations that associate themselves together for mutual advantage and protection, there would not be any question of unpaid accounts or indignant feelings when bills are presented. One of the greatest means or influences that would place physicians on a firm financial basis with other learned professions in regard to their income, as well as enable them to command the respect and esteem of the public, is being more liberal and human in the treatment of each other, banding themselves together in a well-organized society, showing mutual respect for one another's interests and being willing to sacrifice self rather than a fellow practitioner. Physicians have been fighting among themselves too long: the public is too cognizant of their selfishness and petty jealousies, and in the past has used this trait or attitude of jealousy to belittle or discredit the profession.

57. **Treatment of Tuberculosis.**—Inasmuch as Nature, unassisted, slowly and gradually but surely, cures 80 per cent. of all the cases of tuberculous infections among those races in which the disease is and for ages has been most prevalent, and inasmuch as this wonderful achievement, which until recently was incredible, is the result of Nature's methods and processes of inducing immunity, the treatment of tuberculosis in Cornick's opinion should be based on these same principles. He endeavors to secure by well-proved sanatorium methods the speediest arrest of the active progress of the disease. This result he believes can be more quickly and certainly, and, in the long run, more economically accomplished at a sanatorium than at home; but for financial reasons, or for lack of adequate provision, even a three-months' sojourn at a sanatorium is as yet out of reach of many thousands of patients who must be treated at home. Then he would educate each patient along the lines of personal hygiene, sanitation and right living, so that he will not infect others, will not reinfect himself, and will know the simple program of right living best calculated to prevent a relapse, so that, with an arrest of his tuberculous process, he may reasonably hope to live out the allotted span of three score years and ten. This ideal education in right living may be taught outside of a sanatorium, but the patient will acquire it better and more quickly if he goes to school for a time in a well-conducted institution, where he may learn almost as much by association with his fellow pupils, his classmates, as from his instructor; and where his education is the more lasting, because, for a term, he himself lives the ideal life.

64. **Management of Gastric Digestion in Infants.**—The percentage method checked off from time to time by the calorimetric method, is endorsed by Hand in the management of gastric digestion in infants. He gets better results with mixtures of milk, 16 per cent. cream, barley water, granulated sugar and lime water than with any other plan, so modifying the milk that the fat never exceeds 4 per cent., usually 3.5 to 3.8 per cent., rarely giving as low a protein percentage as 1 (usually starting at 1.5 or 1.8, according to age) and increasing it as rapidly as possible, using for the carbohydrates cane sugar and barley water, made from pearl barley, to total 6 per cent. He is sometimes compelled to use peptonization, which he says he likes to do for more than one or two months, classing this with low proteins and the measures mentioned earlier, which interfere with gastric digestion (great alkalinity, sodium citrate, whey, buttermilk) as having the great fault of not developing the digestive powers of the stomach. However, at times these other measures are valuable, and he has sometimes found it necessary to give whey for a time, or buttermilk (and of the two, he prefers the latter made of skimmed milk and fermented with the compressed tablets of the Bulgarian bacillus). These give the digestive organs considerable rest, and at the same time introduce enough nourishment to sustain life for a little while. They may be immediately or gradually supplanted by other mixtures; by adding cream to the whey, or fermenting the whole milk, or the feedings may be alternated.

65. **Diagnostic Value of Gastric Analysis.**—Clarke believes that a suitable test meal properly used may prove in time to be an aid of very considerable value in the treatment of certain of the digestive disturbances of infancy. Before its actual worth is proved, however, a large amount of investigation and practical application of the results on ill children will be necessary. The individual variations in the infant are far greater than in the adult and the correct interpretation of

the results is therefore proportionately more difficult. The most important features in the investigation which are to come must be uniformity, uniformity in method, uniformity in the test meal, uniformity in time and uniformity in the method of analysis.

69. **Influenza on the Pacific Coast.**—Endemic influenza on the Pacific coast, Blum says, resembles the usual type of influenza in that it is an infectious disease caused by Pfeiffer's influenza bacillus, and characterized by inflammation localized especially in the respiratory tract, and by pronounced systemic disturbances. It differs from the recognized type of influenza in two respects, (1) its mildness; (2) its more wide-spread occurrence. Clearly defined, influenza is in general a severe disease, and is accordingly regarded as serious and treated with respect and caution. On the Pacific coast endemic influenza, because of its low fever, freedom from prostration and from immediate danger, appears to be so trivial an affection that it is generally unrecognized as influenza, and, when recognized, is esteemed lightly and treated carelessly. As a result numerous cases are constantly present and widely disseminated. It is particularly common among children. Its spread is unhindered by appropriate prophylaxis. At present it is an insidious, slow-working and seemingly mild affection which, however, keeps alive and active the germ of virulent influenza.

70. **Congenital Stenosis of Ileum.**—The baby in this case was born Nov. 6, 1910, at full term. The baby's bowels moved for the first three weeks two or three times daily. At three weeks constipation was first noticed, a day or two elapsing between movements. At Christmas time the baby went three days and two nights without a movement. After three weeks there was vomiting of "brown" milk, but there was no vomiting of medicines (the medicines were probably all laxatives). Before this period there was some regurgitation of the milk in its natural state. Abdominal enlargement was noted at four weeks; the child was nursed only, and the intervals between nursing were said to be regular. In January, 1911, constipation was the symptom which alarmed the family. The abdomen was markedly distended, the abdominal wall thin, and the coils of intestine were visible on the surface. Reverse peristalsis was noted once during the examination, but never again while the child was under observation. Vomiting occurred just previous to the visit and a cloth on which the child had vomited showed a small streak of matter of a somewhat golden yellow color, resembling that of an infant stool and giving a faint but characteristic odor. This was undoubtedly fecal vomitus. The bowels were constipated, but a small plain water enema gave a fairly good result There was marked emaciation.

The baby was put in the children's ward of the Ellis Hospital where several good evacuations of the bowel were obtained through high enemata. The abdominal distention, however, continued, and the coils of the intestine were still prominently displayed on the surface. Death occurred on Jan. 14, 1911.

At autopsy a narrowing of the small intestine nearly, but not completely, closing the lumen of the bowel was found in the ileum 23 inches above the ileocecal valve. This partial obstruction was apparently congenital. The bowel above was markedly dilated, with a decided increase of the muscle tissue extending more than 2 inches above the point of obstruction. The portion of ileum below was narrow. Water poured into the bowel would slowly work its way through to the portion below. The interesting point in the case, aside from its apparent etiology, was the occurrence of fecal vomiting with apparent ability to freely evacuate the bowels, due, of course, to the fact that the liquid bowel contents could readily, but slowly, pass through the obstruction. At times, however, compensation, so to speak, was lost and a reverse action followed.

82. **Guaiacol and Ichythol as Local Antiseptic.**—For some time Gilbert has been using a mixture containing 1 dram each of guaiacol and ichthyol to the ounce of glycerin as a local antiseptic in the treatment of infected wounds. He says his results have been excellent.

83. **Practical Points Relative to Rabies.**—The method followed at the El Paso Pasteur Institute for the cauterization of wounds is as follows: Apply hot bichlorid, 1-1,000, or boric acid solution to the bitten part, or having soaked it in the same, dry the part; then apply with a cotton wool mop so shaped as to fit the crevices of the wounds, strong carbolic acid solution; immediately take another mop and apply nitric acid, whereupon a slight explosive puff takes place; after this neutralize the nitric acid with a saturated solution of bicarbonate of soda, and wash off with alcohol, which arrests the action of the carbolic acid. Dress the wounds dry, retaining the compress in place by a bandage or adhesive plaster; in some cases collodion application may be used. If the slough or scab is sterile, as is often the case, further application to the wound should be avoided. The compress and bandages may be removed when cleanliness necessitates. The wounds should be allowed to heal under aseptic scab unless complications, i. e., infection, suppuration, etc., prevent.

96 *Case of Missed Abortion. J. Ohlbaum, New York.

89. **Fractures of Femur.**—Gilbert describes a method of treatment of fracture of the femur for which he claims originality of method and apparatus. Extension is continuous, regardless of the position of the patient; elevation of the foot of the bed is unnecessary, and the patient can be turned on the side; adhesive strips applied to the body are more comfortable than counterpressure in the groin and perineum; pain during the application of the apparatus or while wearing

it is almost *nil*, and one attendant can manage the patient. This method is well adapted to any cast for hip, body or femur.

90. **Adenosarcoma of Left Kidney in a Child.**—Pedersen presents the history of a case of adenosarcoma of the left kidney occurring in a child of three years, previously healthy. The important points in this history were the appearance of copious hemorrhages from the bladder and of pain in the left side. It was found that the urine escaped from only one ureter. Operation for removal of the kidney showed that it was an adenosarcoma. The child recovered.

94. **Brill's Disease.**—Louria is inclined to believe that this is not a new disease but a mild form of typhus fever.

95. **Tuberculous Meningitis.**—The patient whose history is is given by King suffered from nervous diseases of functional character for some years before she was taken with coma, followed by an irregular temperature which rose to 107.8 F. Lumbar puncture gave marked lymphocytosis, a positive Noguchi reaction and no tubercle bacilli. The patient suffered from cough for some time before her illness, with loss of weight and general weakness. Rigidity and Kernig's sign were present. No autopsy was allowed.

96. **Missed Abortion.**—The interesting point in this case is that the woman had been carrying a dead fetus *in utero* for probably six and a half months, without it causing her to have any physical disturbance whatsoever. Last menstrual flow occurred in May, 1910. In June, 1910, the woman began to show her usual symptoms of pregnancy, i. e., cessation of menses, which had been punctual outside of her puerperal periods, morning sickness, and the enlargement of the breasts. She consulted several physicians when her menses ceased and was told she had a pregnancy of three months or thereabouts. At about the fifth month from the time her menses ceased she commenced to look for signs of "life," which did not appear. She diagnosed her case as one of early menopause and ceased to give herself a thought about her condition. She was gaining in weight and felt comfortable. On March 12, 1911, at about 3 a. m., she commenced to have cramp-like pains and thought they were her bowels, having eaten some food the night previous which might have caused her to have a "spoiled stomach," as she called it. The pains became more severe and she decided to send for a physician. Ohlbaum was called in and reached her home at 7:30 a. m., March 12. When he got there he was shown a sac which the woman had expelled. On examination he found it contained a fetus of about three and a half months. The fetus, cord and placenta were all connected. Microscopically the placenta showed a fatty degeneration of the entire mass. The fetus was of a dirty, dark, brownish-black appearance.

109 Local Typhoid Epidemic at Murray Bay, P. Q. C. K. P. Henry, Murray Bay.

105. **Typhoid Bacillus Carriers.**—In view of the frequency of typhoid carriers, the difficulty of cure, and the great danger they are to the public health, Meakins urges that every means should be employed for their recognition, prevention and isolation. The task of recognition of transitory carriers falls to the general hospitals, where over 50 per cent. of the cases of typhoid are treated. Every case, before discharge, should be examined thoroughly bacteriologically, and should be kept in the hospital or under strict observation and be treated by homologous vaccines until the excreta are free of typhoid bacilli beyond peradventure. If they could be reexamined six to twelve months afterwards, especially the adult women patients, much would be gained. Search for the source of infection in every case of typhoid, and the district physician should be informed when a known carrier is in his jurisdiction, so that he can keep him under supervision. Those patients who are not treated in the hospitals should be strictly watched and frequently examined by a special department of the board of health.

Germany has dealt with this question in a masterful way. In the southwestern part of the empire typhoid fever is largely endemic. On the recommendation of Koch, stations were established in this district under the municipal government. Each laboratory was well supplied with skilled bacteriologists, who worked in conjunction with the local authorities. Their duties were fourfold—to diagnose typhoid, to ascertain the source of infection in each case and to examine for infected persons, to supervise and regulate the general hygiene of the district, and to make bacteriologic examinations of stools and urine, in order to determine when convalescents cease eliminating typhoid bacilli. By their work they have made great strides in the prevention of typhoid, more especially as regards the typhoid carrier. As there is no other source for malarial infection than mankind, so it is with typhoid, which practically means that if we can prevent, cure or render innocuous the typhoid carrier, we can get rid of typhoid, but not until this has been accomplished.

106. **Infantile Mortality in Canada.**—From the figures given by Hodgetts and the comparisons made, it is quite evident that the infant mortality rate (12 in 100) is not what it should be. It is much too high for a country so sparsely populated, where poverty in its severe forms is non-existent, and the figures quoted carry the conviction that there is a wanton destruction of this item of national resources. Why should the general, infant death-rate be so high, asks Hodgett, when there are not the many social and sanitary problems staring people in the face as have the nations of Europe, and even the United States? Poverty is there, but not to the same alarming extent; unsanitary housing conditions are to be met with, but are not so apparent. The cities are, on the whole, healthy; drainage is good, although in regard to water-supplies and sewage disposal, Hodgetts says, they have yet much to do. Milk-supplies are only fair; that there is room for improvement is shown by the movement being made for improvement is shown by the movement being made for "pure milk." The people, as a race, are fairly healthy; and the climate is looked on as that best suited for an active, vigorous manhood and womanhood.

Hodgetts suggests that the trouble begins in the antenatal period of infant life; that the slaughter of the innocents continues from birth onward, is in evidence; and that much of this wanton destruction could be prevented, is more than certain. In civil law, ignorance is no excuse; how much greater then is the sin of the parents when it must be pleaded that they were ignorant of their duties and responsibilities to their offspring, with the result that the little ones died prematurely. Ignorance of parental duties is a great and growing evil, one which must be met by a better and broader education in all that relates to the child and child life. Young women must be taught the duties of motherhood; young men, the responsibilities of fatherhood; the municipality, the duties it owes to the child in providing for clean housing as well as for proper housing accommodation, pure milk-supplies, and, by civil enactment, seeing that the environment of the mother and child shall be of the best. The state, too, must move along lines which it has already done to improve livestock, to foster our agricultural wealth, spending money for the purpose.

107. **Typhoid at Ottawa.**—Drum concludes that this epidemic was due solely to the infected water-supply. Of course, there were some cases due to contact, and secondary infection through food, but the original and continuing factor was the water-supply.

108. **Fort William Epidemic of Typhoid in 1906.**—The causes of this epidemic are summed up by Douglas as remote and immediate. The remote included: 1. Presence of numerous endemic cases without report of same to the authorities. 2. Systematic pollution of soil and general unsanitary condition of the whole place. 3. Contamination of the water-supply with sewage. The immediate cause was a specific contamination from three main sources: 1. Forde Street sewer, 1,400 feet above the intake, two cases of typhoid. 2. Town pumping-house, four cases of typhoid. 3. Foreign section, 1½ miles above the intake, six cases.

118. **Causes and Treatment of Colds.**—It is Snow's practice to give a medium dose of castor oil or salines between the doses of calomel, if the auto-intoxication is persistent or active and calomel has been used, the aim being of course to prevent cumulative effects from the mercurial. He has used a pill composed of blue mass, colocynth compound, strychnin sulphate and belladonna for ten years, with not one instance of mercurial poisoning, nor one instance tending to show that a constipated habit has been induced. Such a drug combination does not, he says, require an after-flushing with salines, and is sufficiently effective, except in extreme or obstinate cases in which nothing acts so well as calomel.

3 Pancreatic Cyst: Rupture: Recovery. H. Walker.
4 An Intracellular Stage in Development of Trypanosoma Lewisi in the Rat-Flea. E. A. Minchin and J. D. Thomson.

2. **Afferent Fibers in Ventral Spinal Roots.**—Kidd has collected a large amount of evidence, surgical, experimental, histologic and embryologic, which leads him to the inevitable conclusion that afferent fibers, in some cases algetic, in others reflex, exist in the spinal ventral roots of man and many other vertebrates. In his opinion, we ought to divide ventral as well as dorsal roots in cases of intractable pain, except in the case of the third and fourth cervical ventral roots; here division would cause motor palsy of the diaphragm on the side of section; but, unilateral phrenic palsy in man and laboratory animals does not usually cause danger to life. It is, of course, true that ventral root division for pain would always cause some motor palsy, but the patient would probably almost always prefer this disability to a continuance of his pain. The fact that in some cases dorsal root division does abolish all pain suggests that it may be only in some regions of the spinal cord that any afferent fibers pass up ventral roots to their endoneural ganglionic groups of cells.

Certain experiments suggest to Kidd in the clearest manner that the ventral cervical roots of the pigeon, and the ventral roots of the cauda equina of the dog, contain afferent fibers which supply the reflex component of the muscle tonus of the wing muscles and the tail muscles, respectively. The origin of these ventral root afferents in the spinal cord region, whether cervical (pigeon), thoracic and lumbosacral (man), or sacrococcygeal (dog), is entirely from endoneural afferent ganglionic cells, situated, Kidd believes, in (1) the smaller cells of Clarke's column, (2) the solitary cells of the dorsal horn, (3) some of the "middle cells" of the cord, and possibly also (4) some of the cells of the nucleus cuneatus of the bulb. Kidd denies that any motor cells exist in (1) tectum mesencephali, (2) locus coeruleus, (3) Deiter's nucleus, (4) dorsal vago-glosso-pharyngeal nucleus (ganglion), or (5) in any of the four spinal dorsal-zone cell groups mentioned. Since all these parts are developed in the dorsal zone of the embryonic brain or cord (the alar lamina of His), and since, further, there is no instance known in any vertebrate of motor fibers rising in cells derived from the alar lamina, Kidd holds that it is nothing less than a morphologic outrage to teach that any of these cell-groups give origin to motor fibers.

6. **Hereditary Tendency Toward Twin-Bearing.**—Twenty-four patients out of every 2,500 that Oliver has seen have once or oftener given birth to twins, a proportion, that is, of about 1 in 104; therefore he is convinced of the existence of an hereditary tendency toward twin-bearing. In three only of these patients was there no history of twins either on the female or the male side, and in one or more of those it is quite possible that the default may have been due to ignorance. In this group there are twenty-eight sets of twins, as one patient has borne twins three times and two others had each had twins twice. The twins in thirteen instances are boy and girl, in twelve they are two girls, and only in three are they two boys. The aforesaid twenty-eight confinements produced altogether thirty-seven females and nineteen males, a proportion, that is, of practically two females to one male; and this, Oliver says, is fairly constantly the relationship of female to male births as a result of twin conceptions. This is a noteworthy *phenomenon*, since in all European countries,

whether the legitimate and illegitimate births be computed separately or together, the total annual number of male births always exceeds that of females, and this has been a constant revelation year after year in northern and southern countries alike. In England and Wales the total male and female births during the year 1907 were, respectively, 467,728 and 450,314, or proportionally 103 or 104 males to every 100 females. In countries, however, where polygamy prevails this relationship of male to female births is reversed, for polygamy produces about two female births to every one male. This relationship corresponds closely with that noted as a result of twin conceptions.

Judging from his own clinical facts and experience Oliver is convinced that the production of twins in the human female is not a chance affair, and has nothing to do with the deficiency of lime or potash or soda salts in the blood or generative tissues of the mother, for it is well known that deficiency of these salts so alters the sensitivity and irritability of the Fallopian tubes and uterus that well-marked symptoms make their appearance therefrom and abortion is apt to ensue. If, therefore, twin productions were in any way associated with deficiency in the amount of calcium, or potassium, or sodium in the maternal blood, twin productions would more commonly result in abortions than they do.

9. **Meningitis Following Measles.**—During the first half of this year, when an epidemic of an unusually severe form of measles was prevalent, six children suffering from meningitis were admitted into Addenbrooke's Hospital. In one of the patients the disease was primarily pneumococcic. The other five had symptoms of post-basic meningitis. In three of these the cerebral symptoms followed measles, one a week, one six weeks, and one eight weeks after the rash had been seen. In all five the onset of the disease was sudden; most of the patients vomited and rapidly lost consciousness, and retraction of the head and Kernig's sign were well marked. The temperature was usually not above 101 F., and the pulse and respirations were irregular. In three cases improvement followed and seemed to be due to lumbar puncture. One patient recovered completely, and though meningitis was diagnosed it was not proved, as an examination of the cerebrospinal fluid was sterile and showed no excess of cells. The other four patients died and their brains were examined, and all showed a meningitis alike in appearance. There was a greenish-yellow exudation of lymph into the pia-arachnoid membrane at the base of the brain with more fluid than usual in the ventricles. In the cerebrospinal fluid of one patient (who had not had measles recently) the meningococcus of Weichselbaum was found, and in another diplococci were seen in the exuded lymph at the base of the brain. On account of the similarity of the clinical course of the disease and of the appearance of the brains after death, Birt suggests that it is not improbable that the meningococcus was responsible for the meningitis in all the cases. Whether the measles disposed to, or whether it was accidentally followed by, the meningitis is uncertain, but in either case the occurrence of nervous symptoms after measles is interesting on account of its rarity.

15. **Sprue and Ankyiostomiasis.**—The treatment practiced by Macdonald in cases of sprue for many years with marked success consists in the administration of fairly large doses of chlorate of potash at frequent intervals and continued for a considerable period, and treating the diarrhea and dyspepsia by carbonate of bismuth and sulphate of morphin or oxybromid of bismuth. He recommends the following: Chlorate of potash, 1 oz.; water to 12 oz., 1 tablespoonful every four hours after shaking the bottle. The potash does not dissolve in this proportion, but Macdonald thinks there is an advantage in giving some of the undissolved salt in each dose. For the dyspepsia and diarrhea he recommends the following:

℞	Gm. or c.c.		
Bismuthi carbonatis	16		ʒiv
Liquoris morphinæ sulphatis	12	or	ʒiij
Glycerini	16		ʒiv
Aquæ ....q.s. ad	120		℥iv.

M. et Sig.—One dessertspoonful three times daily in water.

This mixture seems to speedily check the diarrhea, and should be then given twice daily, and later at night only until the stools become formed. If the bowels become constipated some aperient pill with blue pill is most suitable. In Macdonald's opinion castor oil and the salines are contra-indicated, as they sometimes cause serious relapses and seem to irritate. The whole treatment can be stopped for a week or so if the case progresses well. Slight relapses are sure to occur, but with continued treatment the relapses get less and less, until complete convalescence is established. Experience has taught Macdonald that a fairly liberal diet can safely be ordered in conjunction with the above treatment. Milk puddings, eggs, soup, bread and butter, underdone meat and white meat, etc., can be given.

17. **New Operation for Hemorrhoids.**—In Chenhall's method each pile is grasped in a pair of long, light, slightly-curved forceps, care being exercised to close the blades just within the mucocutaneous margin and their points on the main vessel in the pedicle above. By drawing the forceps handles toward the lumen of the bowel, the mucocutaneous junction is rendered tense and is divided by a clean-cut knife incision immediately behind the forceps blades to the depth of half an inch. A fine, round, curved needle, threaded with No. 1 plain catgut, is now passed through both sides nearly the full depth of the incision, which is then closed in a direction parallel to the length of the bowel. This suture, when tied, serves as a tractor. Separating the tractor and forceps, the mucous membrane, now rendered tense, is divided by the knife on each side behind the forceps blades. The submucous tissues are carefully raised or divided. The next suture is now inserted. Transfixion of even small veins is easily avoided in passing the sutures, since the floor of the small wound is exposed. This cannot be claimed when sutures are passed through tissues gripped by forceps. Ligature may be, but is rarely, necessary for any vessels. Using, in succession, each suture as a gentle tractor the same procedure is repeated until the upper part of the pedicle is reached. This, which contains the main vessel, is ligatured with No. 2 catgut, divided, tucked down and buried in the end of the incision by a small catgut suture, which closes the upper end of the wound, passing in transit through the end of the incision and the pedicle ligature is rendered additionally secure. This is most important. A long line carrying tied sutures marks the site of the original pile. There is practically no bleeding, and postoperative pain is so slight that sedatives are rarely necessary after the first hypodermic of morphia. Chenhall emphasizes that it is important that sutures be not tied unduly tight. Suppositories should never be used, a dry, sterile dressing pad being the only dressing required. The bowels, carefully prepared before operation, should be allowed to rest until the fourth or fifth day.

23. **Appendix Open at Two Ends.**—The patient, female, aged 28 years, had acute pain and tenderness in the right side. There was no vomiting, but constipation was marked. Since then similar attacks, slighter in character but never with vomiting, have occurred. She noticed at the first attack that she limped with her right leg when walking, and this action relieved the pain. Since her marriage, two years ago, she had a good deal of pain in both iliac fossæ. On abdominal section there was a condition of double salpingitis. The appendix was near the brim of the pelvis, bound down by adhesions to the cecum and adjoining portion of the small

intestine (lower end of the ileum. On separation of the superficial adhesions there was found a hard cord-like adhesion joining the appendix at a point ½ inch from its tip with the ileum. This was inseparable by digital manipulation, and on being cut through was found to enclose the lumen of a short canal which gave access from the appendix to the ileum. The proximal end of the appendix was patent into the cecum, and within the former was a small, hard fecal concretion. The condition evidently pointed to a preexisting appendiceal abscess which had burst into the small intestine, though the previous history scarcely conformed to such an occurrence in severity of symptoms.

30. **Pellagra and Sprue.**—Both pellagra and sprue are afebrile diseases. In both there are emaciation, loss of weight and general malnutrition as later symptoms. The most striking fact, however, is that cases of pellagra may not show any skin manifestations for a very long time, the only evidence present being a persistent and chronic diarrhea, which so closely resembles sprue that one cannot overlook this similarity. Burnet is convinced that the two diseases are one and the same.

38. **Surgery of Hypophysis Cerebri.**—What is known of the surgery of the hypophysis as well as of the functions of this gland is presented in review by Melchior. He emphasizes the excellent clinical results that are obtained from operation, but insists that an early operation in suitable cases offers the only hope of giving the patient relief or of effecting a cure. The headache and the visual disturbances are regarded as a sufficient indication for the immediate performance of the operation

41. **Wassermann Reaction and Experimental Syphilis.**—The Wassermann reaction was sought for 107 times in fifty-five rabbits. The results were always negative. Fifty-four rabbits were infected with syphilis, fourteen through the anterior chamber of the eye and forty-two scrotally. Irrespective of the clinical history of these cases the test was negative. Twenty-five animals were infected by intravenous or intracardial injections; ten presented symptoms of general syphilis. The reaction was positive five times. In two of the animals the reaction was not accompanied by evidence of clinical symptoms. The reaction was obtained as early as the sixth week, but on the average not until the eighth week. The author concludes that his experiments show that a positive Wassermann may be obtained in cases of general infection.

45. **Collateral Circulation of Kidney.**—Liek is convinced that it is impossible to establish a collateral circulation in the kidney by means of decapsulation or otherwise which will equal the normal circulation through the renal artery. He warns against the use of this procedure in the treatment of cases of chronic nephritis.

46. **Actinomycosis of Genito-Urinary Tract.**—Cohn presents the case of a man who, fifteen years previously, was suddenly beset with vesical tenesmus and during this time voided urine containing both pus and blood. The symptoms slowly diminished in severity and after a few years disappeared almost entirely, although the pyuria and hematuria continued. For the past four years there have been present painful urination and dribbling of urine. The patient was pale and very much emaciated. The prostate was enlarged and was believed to be the seat of a purulent inflammation. Cystoscopy did not throw any light on the clinical history of the case. The interior of the bladder was negative. It was concluded, therefore, that while some of the pus might have come from the prostate, the large amount of pus in the urine pointed to a renal involvement to which the bladder inflamma[illegible] secondary. Tubercle bacilli were not found in the p[illegible] fluid nor in the urine but the actinomyces was pres[illegible] large numbers and was successfully cultivated. It was i[illegible] to ascertain the source and method of infection, a[illegible] the patient had worked with cereals and had often slept on straw and hay; he could not recall any injury which might have served as an infection atrium.

47. **End Results of Prostatectomy.**—Casper reports the end results of fifty-four cases of prostatectomy done by him. Reports were received from twenty-six patients as to the condition of the bladder. These patients were operated on two to five years previously and none of them has any difficulty in urination, neither is there any pain. In 95 per cent. of his cases there was cystitis; 75 per cent. of these patients have been freed from this trouble entirely. In all cases in which the renal function was unimpaired before the operation, it remained unchanged after the operation and inasmuch as Casper does not operate unless the function of the kidneys is normal, no kidney disturbances occurred after these prostatectomies. In three cases the patients complained of severe lancinating pains in one or both legs. They resembled the pain of sciatica but disappeared about five months after the operation. Casper suggests that the pain was probably the result of the unavoidable injury done to the nerves of the hypogastric plexus during the operation. In those cases in which the prostatectomy was done because of severe hemorrhages from the prostate, further bleeding was not noted after the operation. In none of the cases was there a recurrence of the original trouble. Naturally, Casper favors operation when it is indicated.

60. **Hydrogen Peroxid in Hyperacidity.**—According to Winternitz, solutions of hydrogen peroxid, even in very slight concentration, reduce gastric acidity but not for any great length of time. He has therefore abandoned this method of treatment and has returned to the use of alkalies.

61. **Determining Gastric Acidity by Means of Roentgen Rays.**—In the procedure adopted by Schlesinger, the patient is fed bismuth mush in any desired form and there is then noted the size of the so-called magenblase or stomach bubble and the rapidity with which the bismuth mush is digested. A roentogram is taken as soon as the bismuth mush enters the stomach. Another picture is taken one hour later. The patient is then urged to drink several ounces of water, containing 10 per cent. of sodium. Two minutes afterward another roentogram is made. This second picture shows a distinct enlargement of the magenblase which is the important part of the procedure. The difference in the size of the magenblase in the first and second pictures shows the amount of CO_2 liberated from the sodium and furnishes the means of estimating the acidity of the gastric contents. The greater the amount of CO_2 the greater is the acidity.

72. **Toxicity of Cholera Vibros.**—The authors ascertained that all of the strains of cholera vibrios obtained during various epidemics occurring in the past three years did not produce any hemotoxins. If, however, organisms grown on blood-serum are used, hemolytic vibrios are produced; therefore methods of culture are recommended for differential purposes; that is, organisms grown in ordinary bouillon media are not hemolytic, whereas blood-serum cultures are hemolytic.

74. **Acetylsalicylic Acid for Cough.**—To allay distressing cough Ebstein gives acetylsalicylic acid. He reports several cases in which only good effects were obtained from this medication. One patient failed to get any relief from the use of codein; Acetylsalicylic acid gave immediate relief. Ebstein says that it not only gives relief but it effects a cure, besides materially shortening the duration of the illness.

76. **Radium Therapy in Carcinoma.**—Arendt recommends radium therapy in those cases in which a radical operation is, beyond question, hopeless, and to prevent recurrence. In the so-called inoperable cases, however, he would remove as much of the carcinoma as possible before resorting to radium therapy. He emphasizes the necessity for circumspection and caution in the use of the radium. Of eighteen cases, ten patients died, eight are living and are now being treated by Arendt. Six of these are in good condition, two are nearing death, three of the patients are following their occupations, the remaining three having the appearance of well persons. In eight cases a complete hysterectomy was performed, four patients had a recurrence. Only one patient of four subjected to radium treatment has had a recurrence. Therefore, Arendt is a firm believer in the use of radium to prevent recurrence after radical operations undertaken to remove a carcinomatous uterus.

77. **Phenolphthalein Blood Test.**—Kober is of the opinion that this test should not be accepted as a positive one, because both positive and negative results are open to question of doubt. He would not use either Meyer's or Fleig's reagent to test for blood.

88 *Th[illegible] in Relation to Tetany in Infants. [illegible] die Epithelkörperchen mit bes. [illegible]ziehungen zur Säuglingstetanie.)

82. **Urobilinuria in Measles.**—Rach and Reuss found urobilinuria in the course of measles in all but four of fifty-one cases, that is, in 92 per cent., but frequently it was slight and transient. It rarely lasted more than a few days and was usually mild, never reaching the intensity of the urobilinuria in scarlet fever. When the urobilinuria was protracted there was always some complication justifying the assumption of insufficiency of the liver. The direct complications of measles did not seem to affect the urobilinuria. It was never observed until toward the end of the eruption phase.

85. **Mumps and the Ear.**—Haike reports the case of a young man of 19 who became suddenly deaf after a few days of malaise and slight fever but no local pain or vertigo. The other features of the case suggested mischief in the labyrinth, and three days later bilateral orchitis developed with high fever and much depression, the young man losing 20 pounds in the course of a month. The mumps seemed to have affected the internal ear first, and permanent deafness has resulted. There was no involvement of the parotid at any time. Gradenigo has reported a somewhat similar case in a boy under 5 years old whose smaller brother had mumps. The older had pains and swelling in the testicles but these subsided under cold applications. The next day sudden deafness developed and was permanent. There were no symptoms on the part of the parotid at any time. In Haike's case there was no known chance for contagion with mumps in the town, but he thinks it should be classed as "epidemic parotitis without parotitis," and believes that this assumption will explain other cases of sudden, bilateral deafness in children, usually accompanied by some mental disturbance at first such as may accompany mumps.

87. **The Cutaneous Tuberculin Reaction.**—Radziejewski writes from the children's clinic at Breslau in charge of von Pirquet to relate the findings at necropsy as compared with the cutaneous tuberculin reaction during life in thirty-nine cases reported in detail and in 327 others. All the data confirm the specific importance of the reaction, and that a negative reaction—in the absence of cachexia, miliary tuberculosis and meningitis—excludes tuberculosis with almost certainty. A positive reaction in infants is almost inevitably of evil prognosis as the active process generally proves fatal and the tuberculous process is never inactive in infants.

88. **The Parathyroids and Tetany.**—Bliss was not able to detect any special connection between hemorrhagic changes in the parathyroids and tetany in children. He examined with the microscope the parathyroids in thirty-five child cadavers from a few months to nine years old, finding them normal in a number of cases and with hemorrhagic changes in others, but with no parallel connection with the convulsions observed in some of the children during life.

89 *Litholapaxy. (145 Litholapaxien.) M. Kreps.
90 *Syphilis of the Bladder. (Die syphilitischen Erkrankungen der Harnblase.) P. Asch.
91 *Tardy Hemorrhage after Nephrotomy. H. G. Pleschner.

89. **Litholapaxy.**—Kreps reviews 145 cases in which he crushed and removed by suction one or more stones in the bladder. Only eight of the patients were females; the ages ranged from 8 to 82 years. He calls attention to the efficacy of long-continued pressure in breaking up even very hard stones. The long pressure changes the *molecular structure* of the stone, so that it crumbles when at first it seemed impossible to produce any impression on it. Even a few minutes' longer pressure may accomplish the desired result. One of his patients was an unmarried woman of 26 who ceased menstruating and the abdomen increased remarkably in size. A pregnancy was assumed but the trouble proved to be a soft phosphate stone entirely filling the bladder and distending it to simulate the pregnant uterus. After the litholapaxy menstruation returned, the patient married and a normal pregnancy followed.

90. **Syphilitic Lesions in the Bladder.**—Asch has encountered three cases of true bladder syphilis and a large number of parasyphilitic bladder affections in the last twelve years, and he compares these experiences with the literature on the subject. The bladder is usually affected, if at all, during the third phase of syphilis. These syphilitic affections of the bladder seldom have a specific aspect and their true nature may be unsuspected. Gummas often simulate papillomas and he suggests that it is wise to examine for syphilis in every case of papilloma of the bladder. Gummatous growths cause manifestations like those from any neoplasm, except that they are liable to induce considerable hemorrhage; the hematuria is distinguished by its continuance from beginning to end of the urination, while with ulcer, even the syphilitic, the hemorrhage is more terminal. Treatment should be the general specific treatment without local measures. General treatment is liable to induce pronounced benefit in tabetic bladder disturbances. Asch cites forty-three recent publications on the subject of syphilis of the bladder.

91. **Hemorrhage After Nephrotomy.**—In the three cases reported by Pleschner the hemorrhage came on suddenly with no premonitory symptoms, the fourth, sixth, twenty-fifth and thirty-third days after the nephrotomy for removal of stones. All bleeding vessels had been ligated, the kidney sutured and *tamponed firmly* from without and the hemorrhage occurred when all was supposed to be progressing ideally. The hemorrhage was arrested in one of the cases under expectant measures but returned again eight days later and more severe. An important aid in diagnosing was the discovery with the cystoscope of the blood spurting from one ureter mouth.

95. **Percussion of the Spine in Differentiation of Compression of the Trachea.**—Stradiotti calls attention to the difference in the findings on percussion of the vertebræ when the mouth and nostrils are open or closed. In a case described in detail certain modifications in the percussion findings were explained by discovery of a tumor in the anterior mediastinum compressing the trachea and causing resonance when the corresponding vertebræ were percussed. Experiments on the cadaver confirmed the importance of this physical sign of compression of the trachea.
